There is a geographic difference in bladder cancer incidence rates across the world, with the highest occurring in Southern and Eastern Europe, parts of Africa, the Middle East, and North America, and the lowest occurring in Asia and underdeveloped areas in Africa (Jemal et al, 2010). Bladder cancer is the 9th most common cancer worldwide, with 357,000 cases recorded in 2002 (Parkin, 2008). Bladder cancer is the 13th most common cause of death, accounting for 145,000 deaths worldwide (Parkin, 2008; Jemal et al, 2010). The incidence rate of bladder cancer has been rising in Asia and Russia because of an increased prevalence of smoking. Sixty-three percent of all bladder cancer cases occur in developed countries, with 55% from North America and Europe. In the United States, the highest bladder cancer incidence rate is in Rhode Island and the lowest is in the District of Columbia (Siegel et al, 2013). The histologic cell type of bladder cancer is very geographically dependent, but urothelial cancer is the most common. In North America and Europe, 95% to 97% of cases are urothelial carcinoma; in Africa 60% to 90% are urothelial and 10% to 40% are squamous cell; and Egypt has the highest rate of squamous cell carcinoma because of the endemic infections with *Schistosoma* species (Parkin, 2008).

Mortality

The mortality rate from bladder cancer in Egypt is three times higher than in Europe and eight times higher than in North America because of the aggressive nature of squamous cell carcinoma that is highly prevalent in Egypt (Parekh et al, 2002). In the United States, death rates for all cancer sites combined decreased by 2.6% per year in males and by 1.8% in females from 2002 to 2004 compared with 1.5% and 0.8% per year in males and females, respectively, from 1992 to 2002 (Siegel et al, 2013). The mortality rate for bladder cancer has decreased by 5% during this period primarily because of smoking cessation, changes in environmental carcinogens, and healthier lifestyles. Better chemotherapy has improved the survival rate in patients with metastatic bladder cancer, and changes in physician practices related to more timely care and more aggressive treatment in healthy patients could lead to improvement in overall survival as well. Lee and colleagues (2006) reported that a delay of more than 12 weeks from the diagnosis of bladder cancer to cystectomy treatment was associated with a decrease in overall and cancer-specific survival. However, more intensive treatment (intravesical chemotherapy and cystoscopy) for patients with noninvasive bladder cancer did not correlate with better survival or reduced need for invasive treatment (Hollenbeck et al, 2009; Morris et al, 2009).

KEY POINTS: EPIDEMIOLOGY

- Bladder cancer is related to age and exposure to environmental carcinogens, primarily smoking.
- The median age of bladder cancer diagnosis is 70 years for men and women, and the incidence of and mortality from the disease increase with age.
- Bladder cancer is less common in African-Americans than in whites; however, the death rate from bladder cancer is higher in African-Americans than in whites.
- The incidence rate of bladder cancer is decreasing faster in men than in women because of the recent decrease in the percent of men smoking compared with women.

Etiology

Bladder cancer is caused by genetic abnormalities and external risk factors, including carcinogen exposure, nutritional factors, fluid intake, alcohol, inflammation, infection, chemotherapy, radiation, and possibly artificial sweeteners.

Genetic Factors

The higher incidence of bladder cancer in white compared with African-American males is probably not genetic but environmental, or it may be related to differential susceptibility to carcinogens (Bouchardy et al, 1995; Wanner et al, 1995; Bouchardy et al, 1996). There are several polymorphisms that seem to be related to the formation of bladder cancer, in particular the susceptibility to environmental carcinogens. *N*-acetyltransferase (NAT) detoxifies nitrosamines, a known bladder carcinogen. Specifically, NAT-2 regulates the rate of acetylation of compounds such as caffeine, which are related to bladder cancer formation. The slow NAT-2 polymorphism is related to bladder cancer with an odds ratio of 1.4 compared with the fast polymorphism (Garcia-Closas et al, 2005). Glutathione-S-transferase (GSTM1) conjugates several reactive chemicals, including arylamines and nitrosamines. The null GSTM1 polymorphism is associated with an increased bladder risk with a relative risk of 1.5 (Garcia-Closas et al, 2005). Null GSTM1 and slow NAT-2 lead to high levels of 3-aminobiphenyl and higher risk of bladder cancer. These polymorphisms are present in 27% of white, 15% of African-American, and 3% of Asian males, thus partially explaining the different bladder cancer incidence rates across ethnic groups.

Heredity. First-degree relatives of patients with bladder cancer have a twofold increased risk of developing urothelial cancer themselves, but high-risk urothelial cancer families are relatively rare (Aben et al, 2002; Murta-Nascimento et al, 2007; Kiemeny, 2008). The hereditary risk seems to be higher for women and non-smokers, but it is not related to secondhand exposure to smoking in families. The inherited risk of bladder cancer formation appears to affect all stages of urothelial carcinoma and is not associated with bladder cancer formation at an earlier age. Unfortunately, there are no clear mendelian inheritance patterns, making classic linkage studies impossible. Most likely, there are a variety of low-penetrance genes that can be inherited to make a person more susceptible to carcinogenic exposure, thus increasing the risk of bladder cancer formation.

External Risk Factors

In addition to the skin and lungs, the bladder is the main internal organ affected by occupational carcinogens. The primary culprits are the aromatic amines that bind to DNA (Deldos and Lerner, 2008; Reulen et al, 2008). Twenty percent to 27% of all bladder cancers are associated with industrial exposure of some type, primarily in areas with a heavy concentration of chemical industries (Case and Hosker, 1954; Blot and Fraumeni 1978; Reulen et al, 2008). Among the first chemical agents implicated in the formation of bladder cancer in dye and rubber workers were benzidine and β -naphthylamine (Case and Hosker, 1954). Other industrial agents implicated in bladder cancer formation include polycyclic aromatic hydrocarbons (PAHs), diesel exhaust, and paint substances (Zeegers et al, 2001).

Environmental carcinogens can enter the system and cause bladder cancer from inhalation or through skin absorption. In general, there is a long latency period of 10 to 20 years between the industrial exposure and the formation of the bladder cancer; thus, proving definitive causative relationships is difficult (Dryson et al, 2008). However, there are a variety of occupations statistically associated with bladder cancer formation, and all are industrial in nature. The overall increased risk of bladder cancer formation in industrial workers is 30%, with agriculture workers having the lowest and rubber workers the highest risk of bladder cancer formation.

Smoking. Tobacco is the main known cause for urothelial cancer formation, particularly cigarette smoking, and accounts for 60% and 30% of all urothelial cancers in males and females, respectively (Brennan et al, 2001; Boffetta, 2008; Gandini et al, 2008; Freedman et al, 2011). The relative risk of developing urothelial cancer from smoking is 2.8 and 2.73 in men and women, respectively (Gandini et al, 2008). Overall there is a two to six times greater chance of developing urothelial cancer with smoking, and the intensity and duration of smoking are linearly related to the increased risk, with no clear plateau level (IARC Working Group, 2004; Boffetta, 2008; Freedman et al, 2011). If a person smokes 1 to 9 cigarettes versus more than 21 cigarettes per day, the relative risk of bladder cancer is 1.5 versus 5.4, respectively (Weir and Dunn, 1970). If a person smokes for 1 to 10 years versus more than 40 years, the relative risk of bladder cancer is 1.2 versus 3.0, respectively (Burns and Swanson, 1991). If a person smokes for more than 60 years, he or she has a sixfold increased risk of developing urothelial cancer compared with a nonsmoker (Burch et al, 1989). Cigars and pipes are probably associated with bladder cancer formation, but there are too few studies evaluating only cigar and pipe smokers because of the high probability that these subjects also smoke cigarettes. The risk of secondhand smoke in bladder cancer formation is low and not statistically different from that for nonsmokers (Zeegers et al, 2002). It is important to note that smoking cessation does make a difference in urothelial cancer formation. Smokers who have stopped for 1 to 3 years have a 2.6 relative risk, and those who have stopped for more than 15 years have a 1.1 relative risk of bladder cancer formation (Wynder and Goldsmith 1977; IARC Working Group, 2004). Smoking is responsible for 30% of all deaths from bladder cancer in males and accounts for 46% of all

bladder cancer deaths in high-income countries and 28% in low- to middle-income countries (Brennan et al, 2000; Parkin, 2008).

Nutritional Factors. Most nutrients or other metabolites are excreted in the urine and have prolonged contact with the urothelium, particularly in the bladder; therefore nutrition plays a role in urothelial cancer formation (Steinmaus et al, 2000; Brinkman and Zeegers, 2008). However, there are inconsistent reports regarding the exact fruits and vegetables that are beneficial in preventing urothelial cancer, suggesting that epidemiologic factors are at play. In general, a Mediterranean diet leads to the lowest urothelial cancer risk. In a case-control study, there were fewer cases of urothelial cancer in the group given a Mediterranean diet versus a standard Western diet, probably because of the increased ingestion of fruits and vegetables (de Lorgeril et al, 1998). Both fruits and vegetables—specifically citrus fruits, apples, berries, tomatoes, carrots, and cruciferous vegetables—contain several active compounds that are important in detoxification. Micronutrients associated with a preventive effect on urothelial cancer formation are mainly antioxidants, including vitamins A, C, and E; selenium; and zinc (Michaud et al, 2000; Zeegers et al, 2002; Schabath et al, 2005; Brinkman and Zeegers, 2008). Fish, rice, and cereal do not seem to have a protective or detrimental effect with regard to urothelial cancer formation (Radosavljevic et al, 2005). Nutritional factors that have been associated with causing or promoting the formation of urothelial cancer include salted and barbecued meat, pork, total fat, pickled vegetables, soy, and spices (Balbi et al, 2001).

Occurrence of urothelial cancer is moderately higher in coffee and tea drinkers, but this may be compounded by smoking or other dietary factors associated with people who drink coffee or tea (Pelucchi et al, 2008). There is no apparent intensity or duration association of coffee and tea ingestion, suggesting an indirect causative effect, unlike for smoking. In conclusion, there are inconsistencies regarding nutritional factors related to urothelial cancer formation, in part because of confounding effects and associations, including coffee ingestion and smoking, ingestion of fruits and vegetables without involvement of smoking, and epidemiologic factors. However, even if not directly causative, there is a very clear association between a healthy diet and a decreased risk of urothelial cancer formation.

Artificial Sweeteners. Some animal studies have shown that large doses of saccharin or cyclamates may influence the development of bladder cancer (Allen et al, 1957; Sontag 1980). These studies are controversial because of the high doses of saccharin and cyclamates provided to the animals and the altered composition of these compounds, which may have influenced the carcinogenic activity found in animal studies (Cohen et al, 1995). Epidemiologic studies in humans have shown no evidence of an increased risk of bladder cancer in consumers of artificial sweeteners (Armstrong and Doll 1975; Morrison et al, 1982).

Analgesic Abuse. Acetaminophen is the active metabolite of phenacetin, a commonly used antipyretic and analgesic. Consumptions of large quantities of acetaminophen or phenacetin (5 to 15 kg during a 10-year period) have been associated with an increased risk of renal cancer and, perhaps, bladder cancer (Piper et al, 1985). However, these studies relied on interviews and questionnaires to ascertain drug exposure rather than actual determination of analgesic use. Kaye and colleagues (2001) performed a nested matched case-control study and found no association between acetaminophen or other nonsteroidal anti-inflammatory drug ingestion and bladder cancer.

Inflammation and Infection. Infection is clearly a contributor to the formation of squamous cell carcinoma in patients chronically infected with *Schistosoma haematobium* and will be covered in the section on squamous cell carcinoma of the bladder (Abol-Enein, 2008). There is a possible link between human papillomavirus (HPV) and urothelial cancer formation. HPV encodes two oncoproteins, E6 and E7. E6 interacts with TP53, which has a role in bladder cancer progression and formation (Westenend et al, 2001). A meta-analysis supports a possible association between HPV infection and bladder cancer, reporting a 2.3 relative risk with confidence intervals (CIs) of 1.3 to 4.1 (Gutierrez et al, 2006). However, the

association between HPV and bladder cancer depends significantly on the method of analysis, the statistical evaluation of the data, proved infection status, and recall bias by the individual. The BK virus is oncogenic in newborn hamsters and can immortalize mammalian cells in vitro (Newton et al, 2005). BK virus can cause severe hemorrhagic cystitis in bone marrow transplant recipients; however, there is no consistent link between BK virus infection and urothelial carcinoma.

Bacterial. Several investigators have suggested that chronic bacterial infections may play a role in bladder cancer formation (Davis et al, 1991). Clinically, chronic catheter use, stones, and infections are associated with bladder carcinoma, but the mechanism of neoplastic formation is not well understood (Abol-Enein, 2008). The mechanism of action may be related to the production of carcinogens such as nitrosamines that can be produced with chronic urinary tract infections (Radomski et al, 1978). In an animal model, rats with a urinary tract infection produce increased urinary levels of N1 N-dimethylnitrosamine over a 24-week period, and this was associated with urothelial hyperplasia and early neoplastic changes in the urothelium. The potential carcinogens were produced primarily with infections caused by *Escherichia coli* and *Pseudomonas*. A retrospective review of published literature suggests that chronic urinary tract infections are associated with bladder cancer, reporting a 1.4 to 1.6 relative risk of developing bladder cancer for any history of urinary tract infection versus none (Abol-Enein, 2008). However, there has been no prospective study examining the association between urinary tract infections and bladder cancer risk. It remains possible that the positive association between infection and urothelial cancer is driven by detection bias or preferential recall between cases and controls. Finally, a large case-control study from the United States based on data from the National Bladder Cancer Study Group reported a relative risk of bladder cancer formation of 4.8 (95% CI 1.9 to 11.5) for subjects with three or more urinary tract infections versus none (Kantor et al, 1984).

Radiation. The potential association between radiation exposure and bladder cancer formation is primarily based on atomic bomb survivors during World War II (Ron et al, 1994; Thompson et al, 1994; Pierce et al, 1996; Hall, 2008). Since 1950, 86,572 people who were exposed to atomic bomb radiation have been followed. Seventy-three percent had a low dose of exposure (less than 50 mSv), and 6% had exposure to very high doses of radiation (more than 500 mSv). There is a significant increased risk of dying from any cancer if a person is exposed to more than 50 mSv. For urothelial cancer, the relative risk of urothelial cancer formation is 1.63 in men and 1.74 in women. It is interesting to note that urothelial cancer formation after radiation is not age related, but the latency period is 15 to 30 years. Further support that radiation can cause bladder cancer is an increased risk of urothelial cancer in patients with prostate or cervical cancer who were treated with radiation therapy (Boice et al, 1988; Neugut et al, 1997; Brenner et al, 2000).

Chemotherapy. Chemotherapy destroys malignant cells by causing significant DNA and cellular damage but can also have a profound effect on rapidly dividing normal epithelium such as in the bladder. The only chemotherapeutic agent that has been proven to cause bladder cancer is cyclophosphamide (Travis et al, 1995; Nilsson and Ullen, 2008). The risk of bladder cancer formation is linearly related to the duration and intensity of cyclophosphamide treatment, supporting a causative role. Phosphoramidate mustard is the primary mutagenic metabolite that causes bladder cancer in patients exposed to cyclophosphamide.

KEY POINTS: EXTERNAL RISK FACTORS

- Bladder cancer is caused by genetic abnormalities and external risk factors.
- Smoking is the most common cause of urothelial cancer.
- A diet rich in fruits and vegetables is protective against bladder cancer formation.

Pathology

Histologically, 90% of bladder cancers are of urothelial origin, 5% are squamous cell carcinomas, and less than 2% are adenocarcinoma or other variants (Lopez-Beltran, 2008). **Urothelial carcinoma is the most common malignancy of the urinary tract and is the second most common cause of death among genitourinary tumors.** At initial presentation, 80% of urothelial tumors are non-muscle invasive. There are multiple growth patterns of urothelial cancer, including flat carcinoma in situ (CIS), papillary tumors that can be low or high grade, and sessile tumors with a solid growth pattern. Non-muscle-invasive cancers can be very large because of lack of genetic alterations required for invasion. Likewise, invasive tumors can be quite small if early genetic changes occur within the tumor cell, allowing for an invasive phenotype.

In 2004, WHO adopted the International Society of Urological Pathology (ISUP)-recommended staging system, which is the standard histologic nomenclature for urothelial carcinoma (Sauter et al, 2004). The clinical pattern of presentation is related to the cytologic and architectural alterations that occur within the tumor. Table 92-1 lists the histologic changes that occur from normal epithelium to high-grade muscle-invasive disease. Box 92-1 lists the neoplasms that can occur in the bladder.

Precursor Lesions to Urothelial Cancer

Normal bladder urothelium is multilayered and less than seven cells thick (Epstein et al, 1998; Montironi and Lopez-Beltran, 2005). The cells mature from the basement membrane to the surface cells in an orderly fashion. The surface has large umbrella cells that may have nuclear atypia and form asymmetrical units. Their membrane is composed of uroplakin proteins and is rigid. These umbrella cells are part of the urine bladder barrier that prevents toxins within the urine from transforming urothelial cells.

Precursor lesions are a continuum from hyperplasia to atypia to dysplasia and finally cancer. Hyperplasia is characterized by markedly thicker mucosa with or without atypia. The urothelium is more than seven cells thick, and there is some disorganization of the cellular architecture. Hyperplasia is often adjacent to low-grade tumors and thought to be a precursor lesion (Epstein et al, 1998). **Loss of parts of chromosome 9 can occur in hyperplasia, particularly if adjacent to low-grade tumors** (Hartmann et al, 1999).

Urothelial dysplasia has abnormal cytologic and nuclear changes that are preneoplastic but are not sufficient to be characterized as CIS (Sauter et al, 2004). Dysplasia is characterized by cohesive cells with mildly abnormal nuclear changes. There is nuclear crowding with prominent nucleoli, and abnormal mitotic figures may be present. Allelic loss of chromosome 9 and occasional TP53 abnormalities in urothelial dysplasia are found (Hartmann et al, 1999; Li et al, 2010). However, dysplasia is a good indication of urothelial instability and a marker of recurrence and progression in those with known urothelial cancer. Isolated dysplasia progressing to CIS occurs in approximately 19% of cases, but dysplasia in the face of previous history of urothelial cancer will form CIS in approximately 60% of cases (Cheng et al, 1999).

Urothelial Cancer Histology

Non-muscle-invasive bladder cancer (NMIBC) includes CIS, papillary urothelial neoplasia of low malignant potential (PUNLMP), and low- and high-grade urothelial cancer that previously had been called *superficial bladder cancer*, which is a misnomer. The clinical significance of the WHO grading classification is shown in Table 92-2. The grade distribution of NMIBC is 25% PUNLMP, 50% low grade, and 25% high grade (including CIS) (Holmang et al, 2001; Samarasinghe et al, 2002). CIS is characterized as non-papillary, flat, high-grade tumors in which the surface epithelium contains cancer cells (Sauter et al, 2004). The cells are large, pleomorphic, and chromatin clumping, and abnormal mitotic figures are common. Loss of umbrella cells is a characteristic, separating CIS from dysplasia. All CIS is high grade by definition. **The genetic**

TABLE 92-1 Histologic Characteristics of Noninvasive Papillary Urothelial Tumors of the Bladder According to the World Health Organization 2004 Classification

PAPILLOMA		PAPILLARY NEOPLASM OF LOW MALIGNANT POTENTIAL	LOW-GRADE PAPILLARY CARCINOMA	HIGH-GRADE PAPILLARY CARCINOMA
ARCHITECTURAL FEATURES				
Papillae	Delicate	Delicate, occasionally fused, not branching	Fused, branching	Fused, branching
Organization of cells	Identical to normal urothelium	Ordered Polarity identical to normal urothelium, any thickness, cohesive	Predominantly ordered, minimal crowding, and minimal loss of polarity; any thickness, cohesive	Predominantly disordered with frequent loss of polarity, variable thickness, discohesive
CYTOLOGIC FEATURES				
Nuclear size	Identical to normal urothelium	May be enlarged but uniform	Enlarged with variation in size	Enlarged with variation in size readily visible
Nuclear shape	Identical to normal urothelium	Elongated, round to oval, uniform	Round to oval, slight variation in shape and contour	Moderate to marked pleomorphism
Nuclear chromatin	Fine	Fine	Mild variation	Moderate to marked variation, hyperchromasia
Nucleoli	Absent	Absent to inconspicuous	Usually inconspicuous	Multiple prominent nucleoli may be present
Mitoses	Absent	Rare, basal	Occasionally at any level	Usually frequent, at any level
Umbrella cells	Uniformly present	Present	Usually present	Usually absent

BOX 92-1 Histologic Type of Tumors of the Urinary Bladder According to the World Health Organization 2004 Classification

Urothelial neoplasia	Pseudosarcomatous stroma
Benign	Stromal osseous or cartilaginous metaplasia
Urothelial papilloma	Osteoclast-type giant cells
Inverted papilloma	With prominent lymphoid infiltrate
Papillary urothelial neoplasia of low malignant potential	Squamous cell carcinoma
Malignant papillary	Usual type
Papillary carcinoma, low grade	Variant
Papillary carcinoma, high grade	Verrucous
Papillary carcinoma with squamous or glandular differentiation	Basaloid
Malignant nonpapillary	With sarcomatoid features
Flat carcinoma in situ	Adenocarcinoma (from bladder mucosa, urachal, with exstrophy)
Invasive carcinoma	Usual intestinal type
Variants of invasive carcinoma	Mucinous (including colloid)
Nested pattern	Signet ring cell
Small tubular pattern	Clear cell
Microcystic pattern	Hepatoid
Inverted pattern	Mixture of aforementioned patterns
Squamous differentiation	Adenocarcinoma NOS
Glandular differentiation	Tumors of mixed cell types
Micropapillary	Undifferentiated carcinomas*
Sarcomatoid carcinoma	Small cell carcinoma
Clear cell urothelial carcinoma	Large cell neuroendocrine carcinoma
Plasmacytoid	Lymphoepithelioma-like carcinoma
With syncytiotrophoblasts	Giant cell carcinoma
With unusual stromal reactions	Undifferentiated carcinoma NOS
	Metastatic carcinoma

*Refers to tumors that are undifferentiated by light microscopy.

NOS, not otherwise specified.

Figure 92-5. High-grade urothelial cancer invading the lamina propria.

abnormalities associated with CIS include alterations to the *RB*, *TP53*, and *PTEN* genes (Cordon-Cardo et al, 2000; Cordon-Cardo, 2008; Lopez-Beltran, 2008). CIS is immunoreactive for cytokeratin 20, and NMP22 is present in the cells. CIS is a precursor lesion for invasive cancer and can spread to the distal ureters and prostatic urethra on the surface or in a pagetoid manner, undermining normal adjacent urothelium (Lopez-Beltran et al, 2002). Endoscopically, CIS is reddish with heaped-up mucosa and can be mistaken for inflammatory changes or radiation cystitis. CIS in association with invasive tumors has a worse prognosis, with a 45% to 65% 5-year death rate (Lopez-Beltran et al, 2002).

PUNLMP is a papillary growth with minimal cytologic atypia that is more than seven cells thick and is usually solitary and located on the trigone (Fig. 92-4) (Holmang et al, 2001; Sauter et al, 2004). PUNLMP is composed of thin papillary stalks, where the polarity of the cells is maintained and the nuclei are minimally enlarged. PUNLMP has a low proliferation rate and is not associated with invasion or metastases, but almost 80% involve loss of chromosome 9 (Cheng et al, 2004). PUNLMP is different from a benign papilloma in that a PUNLMP has a thicker cell layer and large nuclei with occasionally mitotic figures. PUNLMP recurs within the bladder in 35% of patients, but progression is rare, occurring in less than 4% (Oosterhuis et al, 2002).

Low-grade urothelial carcinoma is typically papillary in nature with a fibrovascular stalk and frequent papillary branching with increased cellular size, some nuclear atypia (more than in PUNLMP), and occasional mitotic figures (Epstein et al, 1998). Genetic abnormalities associated with low-grade cancer include deletion of 9q and alterations in *FGFR-3*, *HRAS*, and *PI3K* (Holmang et al, 2001; Cordon-Cardo, 2008). The architectural and histologic changes that

separate low-grade urothelial carcinoma from a PUNLMP include multiple stalks, more cytologic atypia, and the multifocal nature of low-grade carcinomas compared with the solitary PUNLMP.

High-grade papillary urothelial cancer is composed of fused papillary stalks with high-grade cancer in the urothelial layer. A disordered growth pattern, numerous mitotic figures, and pleomorphic cells with exaggerated nuclei are present. Over 80% of high-grade cancers will invade the underlying stroma if left untreated. Genetic abnormalities include deletions of 2q, 5q, 10q, and 18q and gains of 5q and 20q (Knowles, 2008a). Alterations of *TP21* and *TP27* along with *TP53* have been reported.

There are key genetic and phenotypic changes that occur in cancer cells, thus providing the ability to invade the underlying stroma. Invasive urothelial carcinoma is divided into two groups: lamina propria and deep muscle invasion. Lamina propria invasive tumors are high-grade cancers that can be in clusters or in single cells, with single-cell invasion having a worse prognosis (Fig. 92-5). Rarely, low-grade cancers can invade the lamina propria. Vascular invasion can occur within the lamina propria because of the large vascular network within this tissue layer; however, it is frequently overcalled because of retraction artifact around tumor nests. There is a subdivision of lamina propria invasion into T1a (invasion above muscularis mucosa) and T1b (invasion below the muscularis mucosa).

Staging

The American Joint Committee on Cancer (AJCC) in combination with the Union for International Cancer Control meets on a regular basis to determine the tumor, nodes, and metastases (TNM) staging

TABLE 92-3 Definition of TNM

PRIMARY TUMOR (T)

TX

Primary tumor cannot be assessed

T0

No evidence of primary tumor

Ta

Noninvasive papillary carcinoma

Tis

Carcinoma in situ: “flat tumor”

T1

Tumor invades subepithelial connective tissue

T2

Tumor invades muscularis propria

pT2a

Tumor invades superficial muscularis propria (inner half)

pT2b

Tumor invades deep muscularis propria (outer half)

T3

Tumor invades perivesical tissue:

pT3a

Microscopically

pT3b

Macroscopically (extravesical mass)

T4

Tumor invades any of the following: prostatic stroma, seminal vesicles, uterus, vagina, pelvic wall, abdominal wall

T4a

Tumor invades prostatic stroma, uterus, vagina

T4b

Tumor invades pelvic wall, abdominal wall

REGIONAL LYMPH NODES (N)

Regional lymph nodes include both primary and secondary drainage regions. All other nodes above the aortic bifurcation are considered distant lymph nodes.

NX

Lymph nodes cannot be assessed

N0

No lymph node metastasis

N1

Single regional lymph node metastasis in the true pelvis (hypogastric, obturator, external iliac, or presacral lymph node)

N2

Multiple regional lymph node metastasis in the true pelvis (hypogastric, obturator, external iliac, or presacral lymph node metastasis)

N3

Lymph node metastasis to the common iliac lymph nodes

DISTANT METASTASIS (M)

M0

No distant metastasis

M1

Distant metastasis

ANATOMIC STAGE AND PROGNOSTIC GROUPS

GROUP	T	N	M
Stage 0a	Ta	N0	M0
Stage 0is	Tis	N0	M0
Stage I	T1	N0	M0

classifications. The 2009 staging system is shown in [Table 92-3](#) (Edge and Compton, 2010). Ta and CIS disease have no invasion of the basement membrane, but endophytic growth of low-grade tumors into the lamina propria is possible, and cancer can occur in von Brunn nests (Jones et al, 2007; Picozzi et al, 2012). T1 disease, as mentioned earlier, can be divided into T1a and T1b disease (Smits et al, 1998). The subdivision is based on the muscularis mucosa, which comprises thin wavy vesicles of muscle within

the lamina propria that are associated with large vessels and lymphatics. The prognostic significance of T1a and T1b disease is inconsistent because of the lack of muscularis mucosa in many bladder biopsy specimens. Essentially, the T1a and T1b stratifications suggest that the deeper the tumor invades the lamina propria, the worse the survival.

Muscle-invasive disease is subdivided into T2a and T2b. T2a includes invasion into the inner half of the muscularis propria,

whereas T2b is deeper into the outer half. Analysis of the AJCC data would suggest that there is a disease-free survival difference between T2a and T2b disease (Edge and Compton, 2010). T3 disease constitutes invasion outside the bladder proper into the periadipose tissue. T3a disease involves microscopic extension, whereas T3b involves macroscopic extension. Clinically, T3a disease is identified by a palpable mass at the time of examination under anesthesia during the initial transurethral resection and subsequently is non-palpable after the tumor is resected. T3b disease has a persistent palpable mass after transurethral resection of the tumor. Pathologically, T3a disease is microscopic extension into the periadipose tissue, whereas T3b disease is macroscopic extension. T4a disease is invasion of the prostatic stroma, uterus, or vagina, and T4b disease is invasion of the pelvic wall or abdominal wall. **Extension of the tumor into the prostatic urethra without stromal invasion is currently classified under the prostatic urethral section and does not carry an adverse prognosis for patients with known bladder cancer (Pagano et al, 1996; Edge and Compton, 2010).** Prostatic stromal invasion, however, particularly if it is a direct extension from the bladder through the muscle into the prostate, does have a poor prognostic factor, with a 5-year overall survival of less than 25% (Esrig et al, 1996; Pagano et al, 1996).

A major problem in bladder cancer is understaging, occurring in 34% to 64% of patients. Chang and colleagues (2001) reported that 27% of T1 tumors were upstaged after radical cystectomy, and 49% of T2 tumors were upstaged to T3. **Because of this understaging, the American Urological Association (AUA) guidelines call for a repeat transurethral resection in patients with T1 tumors to assess for muscle invasive disease even if muscle was present in the specimen (Hall et al, 2007).**

KEY POINTS: HISTORY AND STAGING

- The WHO 2004 grading scheme should be used routinely.
- The delineation of PUNLMP describes bladder lesions that can recur but rarely invade.
- Low-grade papillary lesions are likely to recur in up to 60% of patients but invade in less than 10% of cases. High-grade lesions also recur; however, invasion and subsequent stage progression can occur in 50% of tumors.
- *Superficial bladder cancer* is a misnomer and should be replaced by NMIBC, which includes PUNLMP, CIS, Ta, and T1 tumors.
- Muscle-invasive bladder cancer leads to death in a significant proportion of patients despite aggressive therapy.

Origin, Recurrence, and Dissemination of Urothelial Cancer

Primary Tumors

The formation of primary urothelial carcinoma is a combination of environmental, genetic, and epigenetic causes. The main environmental factor associated with primary urothelial cancer is cigarette smoking, which is present in one third to one half of all bladder cancers in men and in 30% in women (Brennan et al, 2001; Boffetta, 2008). Smokers have a 2.77 relative risk of developing bladder cancer compared to nonsmokers (Gandini et al, 2008). Other external risk factors are listed above in the section on etiology. These external environmental factors then cause genetic and epigenetic instability that ultimately results in the formation of urothelial carcinoma. **The deletion of parts or all of chromosome 9 is most likely the earliest mutation seen in low-malignant potential NMIBC (Obermann et al, 2003).** There is a known tumor suppressor gene at 9p21 that is a negative regulator of *RB* (Berggren et al, 2003). Another genetic abnormality mutated in 75% of low-malignant potential NMIBC is *FGFR-3* (Billerey et al, 2001; Gomez-Roman et al, 2005). High-malignant potential NMIBC is more likely associated with deletions

of tumor suppressor genes such as *TP53* and *RB* (Chatterjee, 2004a; George et al, 2007; Sanchez-Carbayo et al, 2007). There are a large number of genes associated with stage progression because of the general genetic instability seen in high-grade tumors. It is the accumulation of these multiple genetic alterations, most often caused by external risk factors, that leads to the formation of urothelial cancer.

Recurrent Tumors

A hallmark of urothelial cancer is the high recurrence rate, which approaches 80% for high-malignant potential NMIBC. The two primary theories for recurrent tumor formation are field change effects within the bladder and tumor implantation. **With use of a cDNA expression library, genetic abnormalities seen in CIS can be found in endoscopically normal-appearing urothelium away from the primary tumor (Dyrskjot et al, 2012a).** Similarly, alterations in certain urine markers that are associated with bladder cancer can be found in biopsy-negative bladders from patients with a history of urothelial carcinoma, suggesting that normal-appearing urothelium has the capacity to produce these various tumor markers (Keese et al, 1996; Black et al, 2006). **Multifocality and rapidly recurring tumors are strong prognostic factors associated with finding histologically abnormal urothelium in endoscopically normal-appearing bladder tissue.** In addition, the effectiveness of maintenance bacillus Calmette-Guérin (BCG) therapy in preventing tumor recurrence compared with an induction course only is supportive of field-change effects in the normal-appearing urothelium (Lamm et al, 2000). This suggests that treating the “nonvisible” tumors can prevent or delay the formation of visible cancer.

Tumor implantation during a transurethral resection of the bladder tumor has been suggested as a possible cause for recurrent tumor formation (Soloway and Masters 1980; Pode et al, 1986). The immediate introduction of intravesical therapy, after the tumor inoculation and cauterization, significantly reduced the implantation rate in patients with low-grade urothelial cancer, thus supporting the concept of tumor implantation as a cause of recurrent tumors (Kurth et al, 2000; Sylvester et al, 2004).

Angiolymphatic Invasion

The key phenotypic change that occurs in urothelial cancer that is destined to metastasize is the ability to invade the angiolymphatic system, which is seen in approximately 25% of invasive urothelial carcinoma (Kunju et al, 2008). **Angiolymphatic invasion is a poor prognostic sign with a 40% risk of nodal disease and is an independent predictor of overall and cancer-specific survival (Abdel-Latif et al, 2004; Lotan et al, 2005).** A transurethral resection of the bladder tumor can detect angiolymphatic invasion that is subsequently found in the radical cystectomy specimen 65% of the time. It is critical to use CD-31 and CD-34 monoclonal antibodies with immunohistochemistry to accurately identify the blood vessels in contrast to tumor retraction artifacts (Lotan et al, 2005; Kunju et al, 2008).

Pagetoid Spread

Pagetoid spread occurs when cancer cells grow underneath a layer of normal-appearing surface urothelium (Lopez-Beltran et al, 2002) (Fig. 92-6). Pagetoid spread is primarily seen in urothelial CIS and was first described by Melicow and Hollowell in 1952. Detection of pagetoid spread is difficult because it occurs in approximately 15% of bladders that contain CIS and decreases to 11% in patients with papillary high-malignant potential NMIBC (Orozco et al, 1993; McKenney et al, 2001). Pagetoid spread of urothelial cancer can occur into the prostatic urethra and distal ureters. This is more common after repeated doses of intravesical therapies, and therefore biopsies of normal-appearing prostatic urothelium are needed in the evaluation of patients with positive urine cytology and yet endoscopically normal bladder (Wood et al, 1989a, 1989b).

Figure 92-6. Pagetoid spread of carcinoma in situ (CIS). Large, paler-appearing malignant cells of urothelial CIS (arrows) are spreading as single cells within or undermining the normal urothelium.

Direct Extension

Direct extension of tumors into the basal lamina, connective tissue, and, ultimately, the angiolymphatic system is caused by genetic and epigenetic changes that produce substances capable of invading these tissues. These substances include collagenases, motility and growth factors, and cell adhesion molecules.

There are numerous motility and growth factors present within the extracellular matrix that increase tumor growth. Proepithelin may play a critical role as an autocrine growth factor in the establishment and progression of bladder cancer, and studies suggest that proepithelin may be a novel biomarker for the diagnosis and prognosis of bladder neoplasms (Lovat et al, 2009). The ability of cancer cells to migrate and invade through the extracellular matrix is a critical step for tumor metastasis. Other growth factors associated with bladder cancer invasion include epidermal growth factors (EGFs), transforming growth factor- α , heparin-binding growth factor, and insulin-like growth factor (IGF) (Theodorescu et al, 1998). Cell adhesion molecules are critical for integrity of cell-cell junctions and the inhibition of cell growth. Cell adhesion molecules associated with invasive urothelial carcinoma include E-cadherin, integrins, CD-44, and NCD-44 (Kashibuchi et al, 2007).

Prognostic Factors

There are genetic, pathologic, and phenotypic changes in bladder cancer that are characteristic of poor cancer-specific survival. Overall genetic instability is the hallmark of invasive urothelial cancer, but specifically alterations of *TP53*, *RB*, and *PTEN* carry a very poor prognosis (Chatterjee et al, 2004b). Wang and colleagues (2009) developed a gene expression signature that could accurately segregate poor- and good-risk noninvasive and invasive bladder cancers. They were able to make the segregation even within similar pathologically staged tumors. However, despite the major advances in understanding the genetics of urothelial carcinoma, the stage and grade of the primary tumor is still the strongest predictor of survival. Grade is indicative of the growth potential of the cell, and stage describes the extent of the cancer and the ability to invade. The ability of high-grade tumors to invade and thus metastasize is a result of micrometastatic disease from angiolymphatic invasion. Proliferation markers, such as MIB-1 and PCNA, are found in high-grade tumors and are associated with a worse prognosis (Lopez-Beltran and Cheng, 2003). Alteration in cell cycle regulators, such as cyclins, *TP53*, and *TP27*, leads to increased proliferation as seen

by MIB-1 staining. Ultimately, it will be the integration of stage, grade, and molecular markers that will greatly improve the prognostic determination of urothelial carcinomas and, it is hoped, provide new therapeutic targets.

KEY POINTS: ORIGIN, RECURRENCE, AND INVASION

- Primary urothelial cancer is an environmentally caused tumor that recurs because of persistent genetic changes within the normal-appearing urothelium.
- Recurrent urothelial tumors occur by activation of nascent normal cells that have some genetic instability by environmental factors and tumor seeding during transurethral tumor resection.
- Accumulation of genetic changes leads to cellular proliferation, loss of cell-cell adhesion, and invasion.
- The depth of invasion and grade of the tumor are the best prognostic determinants of urothelial cancer, but molecular assays are likely to be incorporated into future staging schemas.

Molecular Biology

Somatic mutations are more common than germline mutations, and if germline mutations occur, they are associated with a specific type of cancer such as von Hippel-Lindau disease. These somatic and germline genetic changes result in an altered phenotype that can be enhanced or at times be caused by epigenetic alterations, such as promoter methylation or protein degradation, that suppress gene function involved in bladder cancer formation (Wolff et al, 2005).

Specific genetic changes occur between each stage of urothelial tumor development (Cordon-Cardo et al, 2000; Simon, 2004; Cordon-Cardo, 2008). Traditionally, there are two pathways in urothelial cancer formation: normal urothelium to low-grade noninvasive disease, and normal urothelium to CIS and subsequent muscle-invasive disease. A proposed third pathway involves normal urothelium to hyperplasia or dysplasia to high-grade papillary carcinoma and subsequent muscle-invasive disease (Fig. 92-7). Low-grade papillary carcinoma with additional genetic alterations can develop into high-grade papillary disease and subsequent muscle-invasive disease, but it is rare for high-grade tumors to mutate into low-grade cancers. In general, low-grade papillary tumors have genomic stability that allows tumor recurrence but rarely progression. High-grade papillary cancer and CIS have unstable genomes that more readily allow additional genetic alterations needed for muscle-invasive or metastatic disease (Spruck et al, 1994; Knowles, 2006; Lindgren et al, 2006).

The genetic alterations that are the hallmark of low-grade non-muscle-invasive disease are alterations in *FGFR-3* and deletions of chromosome regions 9p and 9q. High-grade invasive disease has infrequent *FGFR-3* mutations but a high rate of *TP53* mutations that approaches 60%. Noninvasive tumors that have both *FGFR-3* and *TP53* mutations are rare and constitute the third pathway to the formation of invasive disease by forming papillary rather than sessile T1 cancer that is derived from CIS (Knowles, 2006; van der Kwast, 2008). Genetic changes that occur in noninvasive and invasive bladder cancers are listed in Tables 92-4 and 92-5, respectively.

Normal urothelium transforms into low-grade papillary cancer through activation of proto-oncogenes, resulting in phenotypic changes that are histologically named *papilloma*, *PUNLMP*, *hyperplasia*, and *low-grade urothelial cancer*. Papillomas lack genetic alterations and have no *FGFR-3* mutations, thus distinguishing this growth pattern from low-grade urothelial carcinoma, and therefore are probably not a precursor lesion to cancer (Knowles, 2006). Conversely, PUNLMP does contain the same genetic abnormalities seen in low-grade urothelial carcinoma, has a proliferation rate

similar to low-grade carcinoma, and is likely to be a precursor to low-grade bladder cancer. Thus there are no clear DNA markers that can distinguish PUNLMP from low-grade cancer (Dyrskjot et al, 2012a). Urothelial hyperplasia is considered a precursor of low-grade carcinoma, and the most frequent genetic deletion is of chromosome 9—most likely the earliest mutation seen in low-grade urothelial cancer formation (Obermann et al, 2003). A variety of tumor suppressor genes are present on both regions 9p and 9q. At 9p21, *CDKN2A* codes for TP16 (INK4A), which is a negative regulator of *RB*, and *TP14ARF*, which is a negative regulator of *TP53* (Berggren et al, 2003). In addition, *CDKN2B* is located at 9p21 and codes for TP15. It is less clear which genes located on 9q are deleted. *PTCH* is located at 9q22, and *DBC1* and *TSC1* are located on 9q33-34 (Aboulkassim et al, 2003; Adachi et al, 2003). The multiple gene losses on chromosome 9 cumulatively lead to the formation of low-grade urothelial neoplasia. It is rare in low-grade papillary cancers to have markers of aggressiveness, such as loss of chromosome 17p, 2q, 4, or 11p (Cordon-Cardo, 2008).

FGFR-3 is related to epidermal growth factor receptor (EGFR), which is not mutated in low-grade cancers but can be overexpressed in low- or high-grade urothelial cancer. FGFR-3 is a tyrosine kinase that causes enhanced growth of bladder cells and is altered in up to 75% of noninvasive low-grade tumors (Gomez-Roman et al, 2005). Altered FGFR-3 can be found in CIS and muscle-invasive disease, although to a much lesser extent, supporting the overlapping nature of tumor formation with multiple genetic changes destined to make either noninvasive or invasive disease. It is interesting to note that *FGFR-3* mutations are also found in seborrheic keratosis, which is a benign papillary skin wart that can be multiple, can recur, but does not invade (Logie et al, 2005). FGFR-3 mRNA is overexpressed eightfold in noninvasive disease and up to fourfold in muscle-invasive disease. Normal urothelium does not produce the FGFR-3 protein, but more than 71% of noninvasive bladder cancers will be immunopositive for the FGFR-3 receptor (Billerey et al, 2001). Because of the differential FGFR-3 expression between normal and cancerous tissue, it could be a therapeutic target (Knowles, 2008b). *FGFR-3* and *HRAS* mutations are mutually exclusive because they are in the same *RAS-MEK-ERK* pathway. Mutations of *FGFR-3* cause constitutive activation of the FGFR-3 receptor and thus signaling through the *MAPK* pathway (Cordon-Cardo, 2008; Knowles, 2008b). *FGFR-3* and *TP53* mutations are virtually mutually exclusive as well, but not because of a common signaling pathway. It is unclear why these two mutations are mutually exclusive, but it does highlight the different pathways in the formation of urothelial carcinoma (Bakkar et al, 2003).

RAS genes are from a family of transforming oncogenes that were originally identified in T24 bladder cancer cell lines (McBride et al, 1982). The most frequent site of *HRAS* activations are mutations in codons 12, 13, 59, and 61 that result in increased enzymatic activity. *HRAS* mutations occur in 40% of urothelial carcinoma, and mutations in codon 12 are the most common (Czerniak et al, 1992). Point mutations in *PIK3CA* are found in 10% of noninvasive bladder cancer and are critical in the *PTEN* pathway (Cairns et al, 1998). *FGFR-3* and *PIK3CA* work together in a similar pathway, and thus both mutations are often seen in the same tumor. Deletions on 9q activate the tumor suppressor genes *TSC1*, *PTCH*, and *DBC1* (Hornigold et al, 1999; Louhelainen et al, 2006).

The transformation of normal urothelium to high-grade invasive bladder cancer is a continuum from dysplasia to CIS and then invasive disease. The conversion of normal urothelium to dysplasia is associated with chromosome 9 deletions in 75% of cases, abnormal TP53 accumulation in 50%, and increased cellular growth in all cases (Mallofre et al, 2003). The subsequent genetic changes to CIS are most likely deletions of tumor suppressor genes rather than activation of oncogenes, and alterations of *TP53* are the main hallmark of high-grade disease (George et al, 2007; Sanchez-Carbayo et al, 2007). *TP53* is located on chromosome 17p and controls the expression of multiple apoptosis-related genes. The presence of *TP53* nuclear protein overexpression and *TP53* gene mutations occur in approximately 80% of high-grade tumors, including CIS. Primary CIS, which is defined as CIS not

associated with a papillary or invasive lesion, has *TP53* overexpression but lacks deletion of chromosome 9. This is in contrast to secondary CIS, which is associated with papillary lesions, can display alterations in chromosome 9, and has molecular expression profiles similar to the adjacent papillary tumor, thus highlighting the overlapping pathways to invasive disease from flat CIS or the hyperplasia to papillary high-grade disease, and then subsequent muscle-invasive disease (Hopman et al, 2002). Also, the same expression signature that exists for secondary CIS can be found in biopsy specimens of morphologically normal urothelium in the same bladder (Dyrskjot et al, 2004). The retinoblastoma gene (*RB*) encodes for a 110-kD nuclear phosphoprotein that functions as a negative cell cycle regulator (Chatterjee et al, 2004a, 2004b). Undetectable levels of the *RB* protein are associated with poor prognoses and increased tumor growth, presumably by affecting the *E2F* gene pathway. Decreased *PTEN* expression is seen in advanced urothelial cancers and CIS. *PTEN* genetic alterations are an independent predictor of survival in advanced cancer, and altered *PTEN* and *TP53* mutations are associated with aggressive tumor growth (Puzio-Kuter et al, 2009).

The genetic changes that occur between noninvasive and invasive high-grade lesions are essentially in genes needed to invade rather than to grow. The earliest changes seen in T1 disease are deletions of 3p, 5q, 6q, 11p, 16q, and 18q (Cordon-Cardo, 2008). Alterations in the *TP53*, *RB*, and *PTEN* pathways are hallmarks of invasive disease, and the combined alterations of all three pathways carry a much worse prognosis (Chatterjee et al, 2004a, 2004b). Finally, the general genetic instability seen in muscle-invasive disease to metastatic disease makes identification of specific genes associated with this progression difficult to clearly delineate (Knowles, 2008a).

Many investigators are using the genetic changes identified in urothelial cancer to determine the malignant potential of small noninvasive cancers by using molecular staging (van der Kwast, 2008). Through the formation of cDNA expression libraries, 80% of Ta urothelial cancers are correctly staged by their genetic profile. Of the 20% of Ta tumors that were wrongly classified as T1 or T2 by genetic profiling, most had a significantly worse prognosis than the correctly staged Ta tumors (Dyrskjot et al, 2003; Blaveri et al, 2005; Dyrskjot et al, 2012b). A 16-gene expression chip of CIS has been developed to discriminate CIS from normal bladder urothelium, with an 80% sensitivity and a 68% specificity. Unfortunately, gene abnormalities for CIS can be found in normal urothelium, confirming the field-chain effect seen in bladder cancer (Dyrskjot et al, 2012b). The main genetic changes that separate noninvasive from invasive disease, as mentioned earlier, include high *FGFR-3* and low *TP53* mutation rates and general genetic stability. T1 disease has low *FGFR-3* and high *TP53* mutation rates and loss of 17p, 13q, and 8p (Knowles, 2008a). Many of these genetic changes are not necessarily related to invasive potential but instead reflect the different grade of tumor seen in Ta and T1 disease. The separation of T1 and T2 disease by genetic analysis is more difficult because of the overall worsening genetic instability and because both are high-grade tumors. However, T2 tumors have more frequent allelic imbalance of chromosomes 6, 10p, and 22 (Koed et al, 2005). Finally, response to chemotherapy in T2 tumors may be predicted by cDNA profiling of the extracellular matrix metalloproteinase inducer (*EMMPRIN*) and survivin genes, although further prospective studies are required (Als et al, 2007). The accumulation of genetic changes in cell cycle regulation (*TP53*), angiogenesis (*NRP2*), and metastasis suppressors (*RhoGDI2*) eventually leads to the highly malignant phenotype of high-grade urothelial cancer (Aaboe et al, 2006). On the horizon, these genetic signatures of aggressive disease will be used for prognostic and therapeutic intent. Wang and colleagues (2009) developed a multiplex quantitative polymerase chain reaction (PCR) assay that accurately segregated Ta, T1, and T2 bladder cancer into high- and low-risk groups. Using a 57-gene mRNA expression profile, at 2 years the high-risk groups had greater stage progression in each pathologic group. A prospective multi-institutional study is needed to confirm these results but may herald a new staging method.

Detection of Urothelial Carcinoma

Gross, painless hematuria is the primary symptom in 85% of patients with a newly diagnosed bladder tumor, and microscopic hematuria occurs in virtually all patients (Khadra et al, 2000; Alishahi et al, 2002; Wallard et al, 2006). The hematuria is usually intermittent and can be related to Valsalva maneuvers; therefore any episode of gross hematuria should be evaluated even if subsequent urinalysis is negative. Fifty percent of patients with gross hematuria will have a demonstrable cause, 20% will have a urologic malignancy, and 12% will have a bladder tumor (Khadra et al, 2000). The risk of malignancy in patients with recurrent gross or microscopic hematuria who had a full, negative evaluation is nearly zero within the first 6 years (Khadra et al, 2000). This should be considered when recommending repeat evaluations for patients with recurrent hematuria.

A full hematuria evaluation for bladder cancer includes cystoscopy, urine cytology, upper-tract imaging (primarily a computed tomography [CT] scan of the abdomen and pelvis), and a prostate-specific antigen (PSA) blood test. A PSA blood test is recommended because 10% of patients with recurrent gross hematuria will have prostate cancer (Mishriki et al, 2008). Microscopic hematuria is typically asymptomatic and carries a 5.4% risk of urologic malignancy and a 4.1% risk of bladder cancer (Mishriki et al, 2008). For patients with a negative microscopic hematuria evaluation, 84.5% never had a recurrence, and of those with repeat microscopic hematuria, none had a urologic malignancy with a 13-year follow-up (Mishriki et al, 2008). The AUA guidelines for evaluation include cystoscopy, upper tract imaging, and urine cytology (Grossfeld et al, 2001). The guidelines recommend consideration for re-evaluation of low-risk patients with microscopic hematuria, but repeat evaluation every 6 months with urinalysis, cytology, and blood pressure (to detect renal disease) is recommended for high-risk patients.

The main diagnostic tests for bladder cancer are cystoscopy and biopsy. White light cystoscopy (WLC) is the gold standard; flexible office cystoscopy is as reliable as rigid endoscopy (Grossfeld et al, 2001) and has excellent sensitivity and specificity for papillary tumors but is relatively poor for CIS. Cystoscopy with porphyrin dye (commonly referred to as *blue light cystoscopy*) may be more sensitive in the detection of CIS (Fradet et al, 2007; Grossman et al, 2007). Porphyrin-induced fluorescence cystoscopy uses photoactive porphyrins, such as hexaminolevulinate, that accumulate preferentially in neoplastic tissue and emit red fluorescence under blue-wavelength light. This may improve the detection of small papillary lesions and CIS. A phase 3 trial evaluating WLC and blue light cystoscopy in patients with known or suspected tumors was completed (Grossman et al, 2007). Blue light cystoscopy detected 58% of CIS compared with 15% for WLC. However, at the patient level, the sensitivity of blue light was 87% and was 83% for white light. Blue light cystoscopy has a false-positive rate of 39% (Fradet et al, 2007). The true impact of blue light cystoscopy on the detection of bladder cancer is unclear, and further studies are required to determine its exact clinical role.

Narrow-band imaging (NBI) is an endoscopic optical image enhancement technique that enhances the contrast between mucosal surfaces and microvascular structures without the use of dyes. The depth of light penetration into the bladder wall increases with increasing wavelength. NBI illuminates the mucosal surface with light of a narrow bandwidth in the blue (415 nm) and green (540 nm) light spectrum, which are strongly absorbed by hemoglobin. Consequently, the vascular structures appear dark brown or green against a pink or white mucosal background. Commercially available systems have integrated NBI and WLC, allowing activation of the NBI wavelengths with the push of a button. Herr and Donat (2008) performed white light and NBI cystoscopy in 427 consecutive patients with a history of NMIBC. Of the 103 patients with a tumor recurrence, 56% had additional tumors identified with NBI compared with use of WLC, and in 12% of patients, the recurrent tumor was found only with NBI. For WLC and NBI cystoscopy, the overall sensitivities were 87% and 100% and the

overall specificities were 85% and 82%, respectively. A recent study suggests that NBI more accurately detects tumor recurrence after BCG therapy than do urine cytology or WLC, and NBI can obviate the need for random bladder biopsies in post-BCG bladders (Herr and Donat, 2008). NBI detected tumor recurrence in 21 of 22 patients with tumor recurrence after BCG, but another 10 patients had a false-positive NBI, resulting in unnecessary biopsies. Because the NBI and WLC are performed by the same urologist, observation bias may skew these results.

Random bladder biopsies are recommended to detect unsuspected CIS or small papillary tumors in endoscopically normal urothelium. Overall, there is a 2.5% detection rate of CIS or small papillary tumors in specimens from random biopsies of patients with known or suspected bladder tumors (Fradet et al, 2007). For patients with concurrent bladder tumors, a random biopsy will detect dysplasia or CIS in up to 23% of cases (Mufti and Singh, 1992). It is reasonable to perform random biopsies in high-risk individuals, such as those given postintra-vesical therapy or those with a positive cytology and an endoscopically negative bladder. Urine cytology, first introduced by Papanicolaou in 1945, evaluates the morphologic changes associated with bladder cancer and is the gold standard urinary marker against which other markers are held (Papanicolaou and Marshall, 1945). Overall, the sensitivity and specificity of cytology in detecting bladder cancer are 40% to 62% and 94% to 100%, respectively (van Rhijn et al, 2005; Volpe et al, 2008). Positive urine cytology is virtually diagnostic of a bladder tumor, although there are cases in which the tumor is not endoscopically visible. The sensitivity and specificity of urine cytology are dependent on the cytopathologist, the number of samples evaluated, and the stage and grade of the tumor (Volpe et al, 2008). Instrumented urine during cystoscopy has improved sensitivity and specificity, but an invasive procedure is required (Badalament et al, 1987). Fifteen percent of patients with atypical cytology that is not diagnostic of cancer have an underlying malignancy (Novicki et al, 1998). Thus patients with atypical cytology need more frequent evaluation or repeat random bladder biopsies.

Urine Markers for Urothelial Cancer

Van Rhijn and colleagues (2005) conducted a systematic literature review evaluating urine marker studies for surveillance only and included markers that had been evaluated in at least two studies published from two separate institutions (Table 92-6). We will discuss the markers that had at least 70% sensitivity and specificity plus novel markers that may be important in the future. The sensitivity and specificity of these tests are lower in patients undergoing surveillance evaluations with no active tumor or those with low-grade cancers (van Rhijn et al, 2005; Zwarthoff, 2008).

NMP-22 is a nuclear matrix protein that is used to form the cell nuclei. NMP-22 is shed into the urine and has a 20-times higher concentration in the urine of bladder cancer patients than in non-cancer controls (Keese et al, 1996). There are a variety of NMP-22 cutoff levels for bladder cancer detection, but typically a level of 10 units/mL is used to identify patients with or without cancer (Soloway, 1996; Grossman et al, 2006). A lower cutoff level of 5 units/mL improves the sensitivity but significantly worsens the specificity. The cutoff level does not appear to be related to stage or grade of the disease. False positives with NMP-22 can occur from patients with an active urinary tract infection or significant hematuria (Atsu et al, 2002). Grossman and colleagues (2006) reported a large multi-institutional study evaluating the efficacy of using NMP-22 as a marker. With use of a cutoff level of 10 units/mL, the overall sensitivity and specificity for detecting urothelial cancer were 49% and 87%, respectively. The sensitivity for Ta, T1, and T2 tumors was 36%, 65%, and 88%, respectively. A combination of cystoscopy and NMP-22 detected all but one of the 103 tumors seen in this study. NMP-22 picked up eight of the nine tumors missed by WLC. NMP-22 appears to be an adjunct to WLC in approximately 10% of patients.

The Lewis blood group antigen X is usually absent from urothelial cells in adults except for occasional umbrella cells (Sheinfeld

From van Rhijn BW, van der Poel HG, van der Kwast TH. Urine markers for bladder cancer surveillance: a systematic review. *Eur Urol* 2005;47(6):736–48.

et al, 1990). There is increased Lewis X expression in bladder cancers, and it is independent of secretor status, grade, and stage. The sensitivity and specificity for the detection of bladder cancer are 75% and 85%, respectively. There is no commercially available test to date. CK 20 and CYFRA 21.1 are fragments of cytoskeletal proteins that can be detected in the urine of bladder cancer patients by either protein or mRNA detection (Ramos et al, 2003). CK 20 has a sensitivity and specificity of 85% and 76%, respectively. A recent multicenter study of 446 patients evaluating the role of CYFRA 21.1, with a cutoff value of 4 ng/mL, found a sensitivity and specificity of 43% and 68%, respectively (Fernandez-Gonzalez et al, 2008). Unfortunately, none of the Ta tumors were identified at the 4-ng/mL cutoff. Decreasing the CYFRA 21.1 cutoff to 1.5 ng/mL increased Ta detection to 33%, but the specificity dropped to an unacceptable 43%. Therefore it is not felt to be a useful marker in the current form, or at least not for low-grade disease.

FISH identifies fluorescently labeled DNA probes that bind to intranuclear chromosomes. The current commercially available probes evaluate aneuploidy for chromosomes 3, 7, and 17 and homozygous loss of 9p 21 (Zwarthoff, 2008). The median sensitivity and specificity of FISH analysis are 79% and 70%, respectively (van Rhijn et al, 2005). A recent prospective study of 250 patients evaluated the role of FISH analysis for identifying recurrent urothelial cancer (Yoder et al, 2007). FISH detected 25 of 39 concurrent tumors, and 35 tumors occurred later in 56 patients who initially had a positive FISH test result. The authors suggested that this was an anticipatory finding. Another study, by Moonen and colleagues (2007), evaluated 105 patients with urothelial cancer. The sensitivity for Ta, T1, and T2 tumors was 26.7%, 60%, and 50%, respectively. These lower sensitivity findings were confirmed (Gudjonsson et al, 2008). It appears that FISH analysis is moderately useful for high-grade disease and may be anticipatory of new tumor formation; however, because of the recurrent nature of noninvasive bladder cancer, it is difficult to tell whether the FISH test was identifying chromosomal abnormalities present in normal-appearing urothelium or if it yielded false-positive results. Multiple markers are available to identify short DNA repeats present throughout the chromosomes that are lost in some tumor cells. Microsatellite analysis amplifies these repeats in the genome that are highly polymorphic, and PCR amplification can detect tumor-associated loss of heterozygosity by comparing the peak ratio of

the two alleles in tumor DNA in the urine sample with the presence of the alleles in a blood sample from the same individual (Wang et al, 1997). The sensitivity and specificity of microsatellite analysis for the detection of urothelial carcinoma range from 72% to 97% and 80% to 100%, respectively (Wang et al, 1997). A European study evaluated microsatellite analysis in voided urine samples for the detection of low-malignant potential non-muscle-invasive urothelial carcinoma (van der Aa et al, 2009). They report sensitivity and specificity of 58% and 72%, respectively. Microsatellite analysis missed only one T1 high-grade urothelial cancer. It is interesting to note that if the microsatellite analysis was persistently positive, there was an 83% 2-year recurrence rate, but if the analysis was persistently negative, only 22% of patients had recurrent tumors. It is hoped that standardization of the test will allow analysis without a blood sample, and this will significantly improve the patient's acceptance.

CpG dinucleotide islands cluster around promoters in an unmethylated state to allow gene expression (Knowles, 2007). Methylation of the CpG islands shuts down the promoter, and, if the promoter in question is part of a tumor suppressor gene, then cancer can form. Examples of promoter methylation of CpG islands causing epigenetic changes in urothelial cancer include the *P16/CDKN2A* gene (Gonzalez-Zulueta et al, 1995). The sensitivity of gene methylation for the detection of bladder cancer is 75%; however, methylated CpG islands can be found in the normal urothelial cells of older patients (Yates et al, 2006). *FGFR-3* point mutations are found in 75% of NMIBC, particularly in Ta tumors (van Rhijn et al, 2004; Wolff et al, 2005). Unfortunately, there are more than 11 different point mutation sites within this gene, and therefore identification of all possible mutations is difficult in a single urine sample. Single-strand conformational polymorphism can detect these point mutations, and a snapshot assay has been produced that holds the possibility for rapid identification of *FGFR-3* mutations (van Oers et al, 2005). Surface-enhanced laser desorption/ionization (SELDI) mass spectroscopy of urine samples has a sensitivity and specificity for detecting bladder cancer of 50% to 90% and 60% to 90%, respectively (Vlahou et al, 2001). Tumor grade, patient age, and type of analysis are confounders of SELDI analysis, and a multi-institutional trial is needed to determine its effectiveness in identifying urothelial carcinoma. Survivin is an anti-apoptotic protein that has a high expression in urothelial cancer

(Smith et al, 2001). Survivin is found in 10% to 30% of bladder cancers and is readily shed into the urine. The sensitivity and specificity of survivin in the detection of urothelial tumors are 64% to 100% and 87% to 93%, respectively (Smith et al, 2001; Shariat et al, 2004). This test may be useful in predicting which patients will respond to intravesical therapy (Hausladen et al, 2003). Survivin was relatively poor at detecting advanced-stage or high-grade tumors, with a sensitivity of 71% for stage T2 tumors and 80% for high-grade cancers (Shariat et al, 2004). Hyaluronic acid controls intercellular communications and cell replication. Urothelial cancer induces hyaluronic acid production from fibroblasts, and the amount correlates with the stage of the disease. The sensitivity and specificity of hyaluronic acid for detection of bladder cancer are 91% to 100% and 84% to 90%, respectively (Pham et al, 1997; Lokeshwar et al, 2002). The sensitivity and specificity for discriminating between low-grade and high-grade lesions are unclear. Telomerase resides at the terminal ends of the chromosomes and duplicates random DNA repeats to prevent cell death (Rhyu, 1995). Telomerase activity is measured via telomeric repeat amplification protocol (TRAP) and is detected in 80% of urine from patients with bladder cancer with no grade differential. The sensitivity and specificity are 90% and 88%, respectively (Sanchini et al, 2005). The ImmunoCyt test (DiagnoCure, Quebec, Canada) detects mucin-based antigens that are present on most bladder cancer cells. The sensitivity and specificity are 61% to 92% and 71% to 90%, respectively (Halling et al, 2000; Pfister et al, 2003).

Virtually all patients report pain and discomfort with office cystoscopy. Urine marker studies could obviate this pain in select situations as described earlier. However, patients reported that a urine marker study would need 90% sensitivity to replace office cystoscopy (Vriesema et al, 2000). The primary concern is missing tumor cells by relying on the urinary marker. None of the currently available urinary markers meet this 90% sensitivity on a reliable basis, and therefore a combination of cystoscopy with urine markers, in select situations, is appropriate for surveillance of patients with NMIBC.

KEY POINTS: DETECTION OF UROTHELIAL CANCER

- Painless gross hematuria occurs in 85% of patients with bladder cancer and requires a complete evaluation that includes cystoscopy, urine cytology, CT scan, and a PSA blood test.
- Patients with microscopic hematuria require a full evaluation, but low-risk patients do not require repeat evaluations. High-risk individuals primarily are those with a smoking history and should be evaluated every 6 months.
- WLC with random bladder biopsies is the gold standard for tumor detection, but blue light cystoscopy may be an adjunct.
- There are various urine markers that can be used to evaluate secreted proteins or shed cells in the hope of noninvasively detecting bladder cancer. To date, none of these markers has a high enough sensitivity or specificity to replace office cystoscopy.

Prevention of and Complementary Medicine Treatments for Urothelial Cancer

Bladder cancer is primarily caused by urothelial exposure to carcinogens in the environment. The long lag time between carcinogenic exposure and subsequent bladder cancer formation makes testing of preventive measures difficult. Prevention of urothelial cancer is a high priority because it is the most expensive cancer to treat for several reasons, including that most urothelial cancer patients do not die from the disease, there is a high recurrence rate, and the primary mode of cancer control is repeated surgical procedures (Botteman et al, 2003; Siegel et al, 2013). There are three

avenues to cancer prevention: primary prevention or avoidance, prevention of malignant transformation of premalignant lesions, and prevention of tumor recurrence. Because there are no well-defined premalignant lesions in bladder cancer formation, most research has centered on primary tumor prevention and prevention of recurrent tumor.

Smoking cessation is the primary mode to prevent urothelial carcinoma. Smoking is responsible for 30% to 50% of all bladder cancers in males, and smokers have a twofold to sixfold higher chance of getting bladder cancer than nonsmokers (Boffetta, 2008; Freedman et al, 2011). Smoking cessation will decrease the risk of eventual urothelial cancer formation in a linear fashion. After 15 years of not smoking, the risk of cancer formation is the same as for someone who never smoked (IARC Working Group, 2004). The strong influence of smoking in bladder cancer formation prevents accurate determination of other less significant dietary, micronutrient, or lifestyle changes that may alter bladder cancer formation. There have been several animal studies that show calorie restriction prolongs life and prevents cancer (Kuska, 2000). The mechanism is unclear but may be mediated through IGF-1, because calorie-restricted mice given IGF-1 had cancer formation similar to that in normal-calorie mice but more than in calorie-restricted mice without IGF-1 supplementation (Dunn et al, 1997). However, it is difficult to translate these calorie-restriction animal studies to the human setting, because exercise level cannot be controlled. The key seems to be lower caloric intake rather than total body weight, although the two are indirectly related. A randomized breast cancer study evaluated low- versus normal-fat diets in women with recently resected breast cancer. Women on the low-fat diet with aggressive breast cancer had a significantly lower risk of recurrence. This could be the result of a variety of factors, including weight loss, lower caloric intake, and lower insulin levels (Chlebowski et al, 2006). Fruit and vegetable ingestion has been postulated to prevent a variety of cancers, including urothelial cancer. There have been many prospective and case-control studies evaluating fruit and vegetable intake. Most show equivocal results, although one showed a statistically significant difference in bladder cancer rates only in male subjects (Michaud et al, 2000). Citrus fruits, apples, berries, and tomatoes have been shown in some but not all studies to result in a lower risk of urothelial cancer (Brinkman and Zeegers, 2008). Carrots and cruciferous vegetables, particularly cabbage, cauliflower, and kale, have also been implicated as having an inverse relationship with bladder cancer formation. None of these studies has been a randomized trial; therefore whether ingestion of fruits and vegetables leads to a healthier lifestyle that is associated with lower urothelial cancer formation or whether these particular agents have a direct effect on urothelial cancer formation is unclear.

Several studies have evaluated the role of vitamin ingestion in bladder cancer formation. None of the large vitamin trials have shown a decreased risk with regard to primary urothelial cancer prevention (Grossman et al, 2008). A randomized trial of patients with urothelial cancer did show that BCG plus high-dose vitamins significantly prolonged the time of recurrence (Lamm et al, 1994). In this randomized trial of active urothelial cancer patients, all received intravesical BCG plus the recommended dietary-allowed vitamin doses, and half were randomly assigned to high-dose vitamins that included 4000 units of vitamin A, 100 mg of vitamin B₆, 2000 mg of vitamin C, 400 international units of vitamin E, and 90 mg of zinc daily. The high-dose vitamin group had a significantly prolonged time to urothelial cancer recurrence, with a 5-year disease survival rate of 91% compared with 41% in the standard-dose vitamin group ($P = .0014$). To date, follow-up trials have not been conducted to corroborate these results. Micronutrient ingestion has been suggested to decrease the bladder cancer risk.

The urogenesis theory suggests that high fluid intake leads to more micturition and lower concentrations of potential carcinogens in the urine and thus a lower risk of urothelial cancer (Braver et al, 1987). There are conflicting results showing an inverse relationship between fluid intake and urothelial cancer formation, but it is

strongest in women (Michaud et al, 2007). The health professional follow-up study of 48,000 participants found that total fluid intake was inversely related to urothelial cancer formation but only in comparing the highest quintile (>2500 mL) and lowest quintile (<1300 mL) groups (Michaud et al, 2007). Green tea contains polyphenolic compounds that are potent antioxidants—specifically, epigallocatechin-3 gallate, which inhibits urothelial cell growth in vitro (Qin et al, 2007). A large Japanese study of 49,566 men and 54,874 women evaluated the effect of smoking, caffeine, and green tea on urothelial cancer formation during a 15-year period (Kurahashi et al, 2009). As expected, smoking was strongly associated with urothelial cancer formation. Caffeine, in the form of either coffee or green tea, may be associated with urothelial cancer formation, and this effect was strongest in women. Caffeine is a known risk factor for urothelial cancer formation, and the carcinogenic effect of caffeine on urothelial cancer cells may be stronger than the antioxidant effect found in green tea (Pelucchi et al, 2008).

KEY POINTS: PREVENTION

- Stopping or never starting smoking is the best prevention for bladder cancer.
- There are no clear dietary or micronutrient programs to prevent primary bladder cancer.
- BCG plus high-dose vitamins may prevent recurrent bladder cancer.

Histologic Variants of Urothelial Cancer

Urothelial carcinoma of the bladder had previously been labeled transitional cell carcinoma of the bladder because of its known propensity for cellular differentiation into other tumor types, such as squamous cell carcinoma, adenocarcinoma, and clear cell carcinoma. Recently the wider spectrum of histologic variance of urothelial cancer has been identified to include distinct growth patterns of urothelial carcinoma, altered cellular differentiation of urothelial carcinoma, mixed cellular growth patterns, and unusual stromal reactions combined with urothelial cancer growth (Lopez-Beltran, 2008). The more common histologic variants will be discussed. It has been suspected that variants of urothelial cancer may not respond to systemic chemotherapy in a similar manner as traditional urothelial cancer. Although the regimens may be different, especially for small cell disease, the response rate of variants of urothelial cancer is similar to that of traditional urothelial cancer (Xylinas et al, 2012).

Micropapillary Urothelial Carcinoma

Micropapillary urothelial carcinoma was first described in the early 1990s as a tumor growth pattern that occurs in many organs, including bladder, breast, lung, and ovary, usually manifesting at an advanced stage (Amin et al, 1994; Samaratunga and Khoo, 2004). The incidence of micropapillary urothelial carcinoma is 0.7% to 2.2% of all urothelial tumors, with a male-to-female ratio of 10:1 and an average age at diagnosis of 65 years (Amin et al, 1994). Because of the advanced stage at diagnosis, the 5- and 10-year overall survival rate of patients with micropapillary urothelial carcinoma is 51% and 24%, respectively (Kamat et al, 2007). The cancer-specific and overall survival rates are similar, suggesting that most patients died from their cancer (Kamat et al, 2007). The histologic characteristics of micropapillary urothelial carcinoma are similar to papillary serous carcinoma of the ovary that develops delicate filiform processes with infiltrating clusters of micropapillary tumors lacking vascular stalks (Fig. 92-8). Micropapillary urothelial carcinoma is associated with conventional urothelial carcinoma in 80% of cases (Lopez-Beltran and Cheng, 2006). Angiolymphatic invasion is common even in non-muscle-invasive disease, high-

Figure 92-8. Micropapillary urothelial cancer.

lighting the aggressive nature of this cancer. There is a high progression rate from NMIBC to muscle-invasive bladder cancer approaching 70%, with a high subsequent metastatic rate despite treatment (Johansson et al, 1999; Kamat et al, 2007). The most effective treatment for all stages of micropapillary urothelial carcinoma is surgical resection. Treatment with transurethral resection and BCG therapy is ineffective unless the tumor is completely resected (Kamat et al, 2007). As with ovarian cancer, neoadjuvant chemotherapy does not appear effective in micropapillary urothelial carcinoma (Bristow et al, 2002; Kamat et al, 2007). Neoadjuvant chemotherapy may actually worsen survival by delaying therapy when compared with immediate cystectomy. Even in the best of situations, immediate cystectomy for non-muscle-invasive micropapillary bladder cancer has a cancer-specific survival rate of 72% compared with 60% for those treated with transurethral resection of the bladder tumor and BCG followed by cystectomy at the time of progression (Kamat et al, 2007). The best outcomes occurred in those patients who had no residual micropapillary tumor at the time of cystectomy, suggesting that complete resection of the tumor is the key procedure. Patients with locally advanced disease do poorly despite aggressive chemotherapy and surgical resection, with a cancer-specific survival rate of less than 22% at 4 years. There are no specific molecular markers associated with micropapillary urothelial carcinoma; however, these tumors are immunoreactive for epithelial membrane antigen and cytokeratins 7, 20, and 34 (Samaratunga and Khoo, 2004). Micropapillary urothelial carcinoma manifests at an advanced stage, with less than 9% of patients having noninvasive disease and more than 50% having muscle-invasive, nodal, or metastatic disease (Kamat et al, 2007).

Nested Variant of Urothelial Carcinoma

The nested variant of urothelial carcinoma is a rare but aggressive cancer that has a male-to-female ratio of 6:1 and can be confused with benign lesions such as von Brunn nests that are in the lamina propria, cystitis cystica, and inverted papillomas (Holmang et al, 2001). There is little nuclear atypia in the nested variant of urothelial carcinoma, but the tumor cells will often contain areas with large nuclei and mitotic figures (Fig. 92-9). Despite aggressive therapy, the mortality rate from the nested variant urothelial carcinoma is significant, with 70% of patients dying of their disease within 3 years (Terada, 2012).

Clear Cell Variant of Urothelial Carcinoma

Seventy percent of urothelial cancer will have foci of clear cells within the tumor (Lopez-Beltran and Cheng, 2006). These clear cells contain glycogen-rich vacuoles and may be confused with metastatic clear cell carcinoma of the kidney; however, the clear

Figure 92-9. Nested variant of urothelial cancer.

Figure 92-10. Clear cell adenocarcinoma of the bladder. Infiltrating adenocarcinoma, showing acini, nests, and infiltrating single cells composed predominantly of cells with clear cytoplasm.

cell variant does not portend a significantly worse prognosis for urothelial cancers (Fig. 92-10).

Glandular or Adenocarcinoma Differentiation

Mixed tumor differentiation is most common with squamous cell cancer, but glandular differentiation occurs in only 6% of urothelial cancer cases (Lopez-Beltran and Cheng, 2006). Glandular differentiation is defined as the presence of two glandular spaces within the tumor (Fig. 92-11). It is important that these glandular spaces not be confused with lymphatic invasion or with processing artifacts. Mucin production can occur, and tumor cells seem to be floating in the mucin. Adjuvant chemotherapy plus radical cystectomy is the best method of treatment for glandular-differentiated urothelial cancer. Previous data have suggested that neoadjuvant chemotherapy was relatively ineffective against glandular and squamous differentiation for muscle-invasive disease. A recent secondary analysis of the Southwest Oncology Group Trial 8710 of neoadjuvant muscle methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC) followed by cystectomy versus cystectomy alone for muscle-invasive bladder cancer evaluated the effect of neoadjuvant therapy on mixed cellular differentiation of urothelial cancer. Among the patients with mixed tumors, the survival benefit from chemotherapy appeared to be greater in magnitude

Figure 92-11. Adenocarcinoma of the bladder. Transurethral resection of the prostate fragment showing extensive involvement by primary bladder adenocarcinoma. Note presence of cribriform and glandular architecture of tumor (inset).

(hazard ratio [HR] 0.46, $P = .02$) than among patients with pure urothelial carcinoma (HR 0.9, $P = .48$) compared with immediate cystectomy (Scosyrev et al, 2010). This suggests that neoadjuvant chemotherapy is an appropriate treatment before radical cystectomy for patients with invasive mixed differentiation urothelial cancer.

Plasmacytoid Tumor

A plasmacytoid tumor is a variant of urothelial carcinoma that has been recognized by the WHO classification system since approximately 2011. This variant is characterized by plasmacytoid cells with the centric nuclei that often invade through the bladder wall and into the perivesical adipose tissue at the time of diagnosis (Keck et al, 2013). These tumors are usually diagnosed at an advanced stage in part because the onset of hematuria is delayed as a result of the sessile and nonpapillary tumor growth pattern (Wang et al, 2012a). These tumors responded very poorly to systemic chemotherapy, with a survival rate shorter than 27 months on average from time of diagnosis (Keck et al, 2013).

NONUROTHELIAL MALIGNANCIES

Sarcomas

Sarcomas are the most common mesenchymal tumor of the bladder but constitute less than 1% of all bladder cancers (Berkmen and Celebioglu, 1997; Parekh et al, 2002; Dotan et al, 2006). Subclassification of sarcoma is based on histologic variations, depending on the specific malignant cell type (Parekh et al, 2002; Spiess et al, 2007). Leiomyosarcoma is the most common histologic subtype, followed by rhabdomyosarcoma and then, rarely, angiosarcoma, osteosarcoma, and carcinosarcoma. The male-to-female ratio is 2:1, and the average age at presentation is in the sixth decade of life. There are no clear agents that cause bladder sarcomas, although there is an association with pelvic radiation and systemic chemotherapy for other malignancies (Spiess et al, 2007). It is important to note that bladder sarcomas are not smoking related. Genetic abnormalities of leiomyosarcoma are inconsistent and not used in staging or identification. The majority of sarcomas are high grade, and more than 75% are confined to bladder muscle (Rosser et al, 2003; Dotan et al, 2006). The most common presenting symptom is gross painless hematuria in 79%, followed by local irritative symptoms in 16%. Transurethral resection of the tumor, which may appear to have normal overlying urothelium, is necessary for diagnosis along with abdominal and chest imaging. The grade of the

sarcoma is the primary prognostic factor and is incorporated into the overall sarcoma staging system (Dotan et al, 2006). Treatment for localized disease includes radical cystectomy, with a premium on obtaining negative surgical margins because the local recurrence rate is 2.4 times higher in patients with a positive surgical margin (Dotan et al, 2006). The overall 5-year disease-free survival rate for leiomyosarcoma of the bladder is 52% to 62% (Rosser et al, 2003). Other poor prognostic factors associated with sarcomas include angiolymphatic invasion and metastatic disease at the time of presentation. **Active chemotherapeutic regimens are lacking for bladder sarcomas, but doxorubicin, ifosfamide, and cisplatin are the most effective agents** (Dotan et al, 2006; Spiess et al, 2007). The most common site for metastatic disease is the lung, followed by bone, liver, and, rarely, soft-tissue organs. Rhabdomyosarcomas may occur at any age, but in young children, they produce polyploid lesions at the base of the bladder, described as *botryoides tumors*. Multimodality therapy combining chemotherapy with surgical resection and radiation is used in the treatment of pediatric rhabdomyosarcomas (Zanetta et al, 1999).

Signet Ring Cell Carcinoma

Primary signet ring cell carcinoma of the bladder is extremely rare, constituting less than 1% of all epithelial bladder neoplasms (Morelli et al, 2006) (Fig. 92-12). Signet ring cell carcinoma can be of urachal origin and directly extend into the bladder. **In general, these tumors are high-grade, high-stage tumors at presentation and have a uniformly poor prognosis.** The primary treatment is radical cystectomy; however, in the majority of patients there are regional or distant metastases at the time of presentation, and the mean survival time is less than 20 months (Torenbeek et al, 1996). There are reports of elevated carcinoembryonic antigen (CEA) in patients with signet ring cell carcinoma. The prognostic significance of this elevated serum marker is unclear (Morelli et al, 2006). Understaging is very common in signet ring cell carcinoma, with peritoneal studding common at the time of surgical exploration.

Small Cell Carcinoma

Small cell carcinoma primarily arises in the lung but can occur in extrapulmonary sites, including the bladder, prostate, and colon (Thota et al, 2013) (Fig. 92-13). **Small cell carcinoma of the bladder should be considered and treated as metastatic disease,**

even if there is no radiologic evidence of disease outside the bladder. Small cell carcinoma of the bladder accounts for much less than 1% of all primary bladder tumors. In general, small cell carcinoma of the bladder is very chemosensitive, and the primary mode of therapy is chemoradiation therapy. The tumor affects men older than 70 years, and there is a slightly higher prevalence in smokers (Choong et al, 2005). The origin of extrapulmonary small cell carcinoma is unclear, but may be related to multipotential stem cells that can develop into small cell carcinoma within extrapulmonary organs (Thota et al, 2013). The most common presenting symptom is painless gross hematuria; however, local irritation and pain are relatively frequent. At transurethral resection the mass is indistinguishable from urothelial carcinoma, and resection is required to make a histologic diagnosis. Histologically, the common cellular pattern is diffuse sheets of dark blue cells with necrosis and mitosis. Chromogranin A staining is the primary method to distinguish high-grade urothelial carcinoma from small cell cancer of the bladder (Iczkowski et al, 1999). A variety of chemotherapeutic regimens have been used, but therapy with carboplatin or cisplatin and etoposide is the current treatment of choice (Choong et al, 2005). It is common to have a complete response from initial chemotherapy; however, clinical relapse occurs in more than 80% of patients. It is not uncommon to see small cell carcinoma admixed with other histologic types of bladder cancer, including urothelial, adenocarcinoma, and squamous cell cancer (Choong et al, 2005). This supports the stem cell theory of histogenesis, with multipotential undifferentiated stem cells producing small cell carcinoma and other histologic types of bladder cancer. Identical patterns of allelic loss in small cell carcinoma and coexisting urothelial cancers suggest a common clonal origin. Small cell carcinoma of the bladder exhibits both epithelial and neuroendocrine differentiation. Neuron-specific enolase, chromogranin A, and synaptophysin markers help differentiate small cell from urothelial carcinoma (Mukesh et al, 2009). Although chemoradiation therapy is the primary treatment for small cell carcinoma of the bladder, experience combining chemotherapy with radical cystectomy for primary small cell cancers of the bladder has shown equal, or perhaps better, local control and disease-free survival than found with chemoradiation (Quek et al, 2005). However, with 5-year cancer-specific survival rates of 16% to 18% with chemoradiation or chemotherapy and radical cystectomy, respectively, the primary method to improve survival will be more effective systemic therapy.

Figure 92-12. Signet ring cell cancer of the bladder. Infiltrating single tumor cells possess large amounts of pale to clear cytoplasm, with the nucleus being stretched and pushed to the periphery (signet ring appearance).

Figure 92-13. Small cell carcinoma of the bladder. Tumor composed of sheets and nests of basophilic appearing tumor cells with high nucleocytoplasmic ratio. Histologic features resemble small cell carcinoma seen in the lung. Tumor cells stain and show diffuse and strong immunoreactivity with neuroendocrine markers chromogranin (inset) and synaptophysin.

Figure 92-14. Squamous cell cancer with associated urothelial cancer.

Squamous Cell Cancer

Chronic infection with *S. haematobium* or, to a lesser degree, other bacteria leads to squamous cell formation of the bladder (Abol-Enein, 2008). The *Schistosoma* ova are deposited in the wall of the bladder and produce chronic inflammation that converts the urothelium to a squamous cell epithelium. Squamous cell epithelium has a much greater proliferation rate, and, with the presence of chronic inflammation, over time this greater proliferation rate leads to cancer formation. The exact mechanism by which *Schistosoma* ova can cause squamous cell carcinoma is unclear, but two factors are suspected. One is the increased proliferation rate, and the second is the chronic inflammation and exposure to environmental agents. The increased proliferation of the squamous epithelium leads to a higher risk of spontaneous genetic alterations that can cause cancer (Cohen and Ellwein, 1990). A chronic inflammatory process and exposure to environmental agents can combine to generate genotoxic substances in the urine, such as *N*-butyl-*N*-(4-hydroxybutyl)nitrosamine. This substance is generated in very high levels in the urine of patients chronically infected with *Schistosoma* organisms and is a known bladder cancer carcinogen in bladder cancer models (Abol-Enein, 2008). In addition, chronic infection with *S. haematobium* converts nitrates to nitrites and subsequently to nitrosamines, which are known bladder carcinogens. Chronic schistosomiasis leads predominantly to squamous cell carcinoma rather than urothelial carcinoma, with 70% of infected patients who develop bladder cancer having squamous cell carcinoma, although many will have both urothelial and squamous cell cancer (Cohen and Johansson, 1992) (Fig. 92-14). Spinal cord-injured patients are also at risk for developing squamous cell carcinoma, most likely because of chronic catheter irritation and infection. Older studies have suggested a 2.5% to 10% incidence of squamous cell carcinoma in the spinal cord-injured population, with a mean delay of 17 years after the spinal cord injury (Kaufman et al, 1977). More recent analysis of the association of spinal cord injury and bladder cancer formation has shown a remarkably lower risk of bladder cancer formation of 0.38%, most likely because of better catheter care (Bickel et al, 1991). This supports the concept that chronic infection and foreign bodies can lead to bladder cancer formation.

Prostatic Urethral Cancer

Ortega was the first to describe urothelial carcinoma involving the prostatic urethra (Ortega et al, 1953) (Fig. 92-15). Prostatic urethral cancer is associated with urothelial cancer in 90% of patients, primarily CIS, and most will have multifocal bladder tumors. However, the incidence of prostatic urethral disease in patients with primary

Figure 92-15. Urothelial carcinoma in situ (CIS) of the prostate. Urothelial CIS is growing within benign prostatic acini. The size and contour of the prostatic acini are still maintained, with replacement of inner lining of columnar epithelium of prostate by multilayered epithelium of urothelial CIS.

KEY POINTS: HISTOLOGIC VARIANTS

- Eighty percent of urothelial carcinomas will contain some mixed differentiation, most commonly squamous cell.
- Altered growth patterns, particularly micropapillary and nested variants, carry a poor prognosis, even for non-muscle-invasive disease.
- Neoadjuvant chemotherapy appears to be active in mixed tumors containing adenocarcinoma or squamous cell cancer but not against altered growth patterns such as in micropapillary and nested urothelial cancer.
- Small cell carcinoma of the bladder should be treated as metastatic disease with institution of chemotherapy followed by either radiation therapy or surgery for elimination of the local disease.
- Signet ring carcinoma is uniformly understaged and invariably is at local, regional, or metastatic stage at presentation.

urothelial cancer is only 3% (Rikken et al, 1987). Secondary prostatic urethral involvement in patients with a history of urothelial cancer is approximately 15% at 5 years and 30% at 15 years, almost uniformly associated with extensive intravesical therapy (Herr and Donat, 1999). For patients undergoing radical cystectomy for urothelial cancer, the risk of identifying prostatic urethral disease is 40%. Risk factors for prostatic urethral involvement are CIS of the bladder neck and a history of intravesical chemotherapy (Wood et al, 1989a). Most patients with prostatic urethral disease will have direct extension of the bladder cancer into the prostatic urethra; however, some patients will have pagetoid spread underneath normal-appearing urothelium at the bladder neck.

Transurethral resection of the prostatic urethra is the primary method for detecting prostatic urethral carcinoma, with a sensitivity and specificity of greater than 90% (Wood et al, 1989a; Donat et al, 2001a, 2001b). Transurethral resection of the prostatic urethra should be performed on all patients with positive urine cytology but a negative bladder biopsy, or on those with recurrent bladder cancer after multiple courses of intravesical chemotherapy. For patients with noninvasive prostatic urethral cancer, transurethral resection of the prostate with BCG therapy is appropriate (Palou et al, 2007). For patients with prostatic ductal disease, complete transurethral resection of the prostate is warranted, plus BCG

therapy. The current 2009 bladder cancer staging system now excludes noninvasive prostatic urethral disease from the T4 category. These tumors have a relatively good prognosis not consistent with T4 staging status. Prostatic urethral cancer is now staged in a prostatic urethral category in the AJCC staging manual (Edge and Compton, 2010). Only patients with prostatic stromal invasion, either direct or indirect, are considered to have T4a-staged disease. Prostatic stromal invasion occurs in 7.6% to 25% of patients with prostatic urethral cancer (Wood et al, 1989b; Herr and Donat, 1999). Ninety percent of these cases are associated with previous bladder tumors, and almost all patients have had previous BCG therapy. Transurethral biopsy of the prostate is recommended; however, if patients have direct extension of the tumor through the bladder wall into the prostate, a prostate needle biopsy may be warranted (Donat et al, 2001b). Patients with prostatic stromal disease are staged at T4a, and a better prognosis is associated with those who have stromal invasion through the prostatic urethra compared with invasion directly through the bladder wall into the prostate (Esrig et al, 1996). Multimodal therapy combining chemotherapy with radical cystectomy is the appropriate treatment (Palou et al, 2007).

Intravesical Chemotherapy

Refractory High-Grade Disease

Role of “Early” Cystectomy

Surveillance and Prevention

Secondary Prevention Strategies

Traditionally known as *superficial bladder cancer*, **malignant urothelial tumors that have not invaded the detrusor are more appropriately termed *non–muscle-invasive* cancers** (Epstein et al, 1998; Smith et al, 1999). The former term suggested that all such tumors shared the relatively benign course of low-grade papillary tumors, giving misleading reassurance to patients with the highly malignant subcategories of carcinoma in situ (CIS) and high-grade Ta and T1 lesions. **Approximately 70% are non–muscle invasive at presentation. Of these, 70% present as stage Ta, 20% as T1, and 10% as CIS (Fig. 93-1) (Ro et al, 1992).**

The presence of bladder cancer is usually suspected when hematuria occurs. Patients with macroscopic (gross) hematuria have reported rates of bladder cancer of 13% to 34.5% (Lee and Davis, 1953; Varkarakis et al, 1974). Microscopic hematuria is associated with a 0.5% to 10.5% rate of bladder cancer (Golin and Howard, 1980; Mohr et al, 1986; Sultana et al, 1996; Khadra et al, 2000). The presence of irritative voiding symptoms may double that risk, especially for CIS (5% vs. 10.5%) (Mohr et al, 1986). For example, the Mayo Clinic reported that 80% of patients with CIS had irritative symptoms on presentation (Zincke et al, 1985). In a review of 600 patients diagnosed with interstitial cystitis, 1% of the patients had a missed diagnosis of urothelial carcinoma. Of note, two thirds of these patients did not have hematuria (Tissot et al, 2004). Thus cystoscopy and upper tract imaging are indicated in patients with hematuria and/or unexplained irritative symptoms (Grossfeld et al, 2001; Davis et al, 2012).

Recurrence is common in all patients with non–muscle-invasive urothelial cancer (UC) but can often be controlled successfully with transurethral surgery, intravesical therapy, or a combination. In contrast to recurrence, patients can be divided into low or high risk for progression, which is the true concern. Low-grade Ta lesions are low risk, whereas all high-grade lesions (including CIS) have a high risk of progressing. The frequency of progression and death is shown in Table 93-1.

PATHOLOGY: GRADING AND STAGING

Pathologic Grading

Although the World Health Organization (WHO) has determined that the term *urothelial cancer* is preferable to the term *transitional cell cancer* (TCC), the latter remains in widespread use. However, the WHO recommendation to move away from the traditional

grading system (1 to 3, from low grade to high grade) is now accepted by most urologists and pathologists. The WHO recommends that **malignant tumors be classified as low grade or high grade, regardless of invasion status.**

By contrast, essentially benign papillary tumors with orderly cellular arrangement, minimal architectural abnormalities, and minimal nuclear atypia are distinct from those two grades and are designated papillary urothelial neoplasm of low malignant potential (PUNLMP). Such tumors would have been labeled either papillomas or grade 1 TCC in older systems but are now regarded as so unlikely to progress that they are considered benign. However, on the basis of this low risk, the WHO recommends that such pathology reports contain the note, “Patients with these tumors are at risk of developing new bladder tumors (‘recurrence’), usually of similar histology. However, occasionally these subsequent lesions manifest as UC, such that follow-up of the patient is warranted” (Epstein et al, 1998). Papillomas are truly benign and not associated with risk of progression (Figs. 93-2 through 93-5; also see Fig. 93-1).

Pathologic Staging

The bladder has three main histologic layers: (1) urothelium, (2) suburothelial loose connective tissue called *lamina propria*, and (3) detrusor or muscularis propria (which is absent beneath the urothelium of diverticula). Stage Ta denotes a papillary tumor confined to the urothelium, regardless of grade. CIS (also termed *Tis*) is a flat, high-grade lesion confined to the same layer, and T1 is a tumor invading lamina propria. The TNM grading system is illustrated in Figure 93-1.

The demarcation between “superficial” and “invasive” has sometimes been errantly considered between T1 and T2. However, **T1 tumors invade the lamina propria by definition, so they cannot be accurately characterized as noninvasive.** Unlike the urothelium, which is devoid of vessels or lymphatics, the lamina propria is rich in both, providing opportunity for metastasis. These tumors sometimes invade the wispy and discontinuous muscularis mucosae of the lamina propria, which can be confused for muscularis propria (detrusor) during pathologic interpretation. **Imprecise verbiage on the pathology report can lead the urologist to misinterpret invasion of muscularis mucosae to be muscle invasive, risking an overstaging error.** Direct communication between urologist and pathologist is essential when this occurs.

TABLE 93-1 Estimates of Disease Progression in Non-Muscle-Invasive Bladder Cancer: World Health Organization/International Society of Urologic Pathology Consensus Classification

TUMOR TYPE	RELATIVE FREQUENCY (%)	PROGRESSION (%)	DEATHS (%)
NONINVASIVE			
Papilloma	10	0-1	0
Papillary urothelial neoplasm of low malignant potential	20	3	0-1
Papillary cancer, low grade (TaG1)	20	5-10	1-5
Papillary cancer, high grade (TaG3)	30	15-40	10-25
INVASIVE			
Papillary cancer (T1G3)	20	30-50	33
CARCINOMA IN SITU			
Primary	10	>50	—
Secondary	90	—	—

From Donat SM. Evaluation and follow-up strategies for superficial bladder cancer. Urol Clin North Am 2003;30:765–6.

Figure 93-1. Carcinoma in situ is a high-grade, flat malignancy confined to the urothelium. Papillary tumors confined to the urothelium are Ta, whereas papillary tumors invading lamina propria are T1. The T1 tumor here intertwines with the wispy fibers of the muscularis propria but by definition does not invade the smooth muscle fibers of the detrusor. T2 tumors invade the detrusor muscle, and T3 tumors are in extravesical fat as shown.

Figure 93-2. The urothelium is thickened, but cells and nuclei are normal in papillary urothelial neoplasm of low malignant potential (×40).

Figure 93-3. Ta low-grade tumor (×40). Cells are relatively normal but exhibit irregularity and some nuclear differentiation.

Figure 93-4. Carcinoma in situ (×40) exhibits severe irregularity of cellular structure and nuclear pleomorphism, but there is no invasion of lamina propria.

Figure 93-5. T1 ($\times 40$) high-grade tumor exhibits nesting of abnormal cells and mitotic figures. Tumor cells can be seen invading the lamina propria in the lower one third of the photomicrograph.

Deep lamina propria invasion carries a substantially more serious prognosis in some reports, and some have proposed these be subcategorized as T1b (Younes et al, 1990). However, the value of substaging has not been validated in other studies (Platz et al, 1996), so the 1998 Bladder Cancer Consensus Conference Committee rejected the concept (Epstein et al, 1998).

Tumor Biology

Low-grade tumors rarely invade the lamina propria or detrusor, so invasive tumors may be almost equated with high-grade histology. However, tumors of all grades and degrees of potential aggressiveness can be identified before invasion, so no such grading assumption can be made about these lesions.

Low-grade Ta lesions recur at a rate of 50% to 70% and progress in approximately 5% of cases. In contrast, high-grade T1 lesions recur in more than 80% of cases and progress in 50% of patients within 3 years. This behavior is primarily grade, rather than stage, dependent, because high-grade tumors progressed with similar frequency regardless of whether they were invasive (T1) or noninvasive (Ta) (Herr, 2000b). Prognosis also correlates with tumor size, multiplicity, papillary versus sessile configuration, presence or absence of lymphovascular invasion, and status of the remaining urothelium (Althausen et al, 1976; Lutzeyer et al, 1982; Heney et al, 1983a, 1983b; Kunju et al, 2008).

The variance in biologic behavior for low-grade versus high-grade lesions correlates with the known dual molecular lines of genetic development for these two pathways and supports the concept that high-grade and low-grade cancers may be considered as essentially different diseases (Hasui et al, 1994; Droller, 2005). Chromosomal alterations caused by oxidative DNA damage create two separate genetic pathways to the development of UC (Spruck et al, 1994; Richter et al, 1997; Cote and Chatterjee, 1999). The first and more common (low grade) leads to noninvasive, papillary tumors. These usually follow an indolent course unless they convert to or are associated with a tumor of the second pathway (Kiemeny et al, 1993).

The second pathway leads to the development of high-grade cancer including CIS, T1, and, ultimately, muscle-invasive carcinoma. Such genetic alterations can be evaluated using karyotyping, microsatellite analysis for allelic imbalance (Mao et al, 1996), comparative genomic hybridization (Kallioniemi et al, 1995), DNA ploidy analysis by flow cytometry (Bittard et al, 1996), and fluorescence in situ hybridization (FISH) (Degtyar et al, 2004). These evaluations can show that low-grade papillary tumors tend to exhibit relatively few chromosomal abnormalities, primarily involving loss of all or part of chromosome 9 (particularly the q arm, which holds tumor-suppressing loci). In contrast, high-grade tumors tend to have numerous and greatly variable chromosomal gains and losses. In addition to their relatively predictable aneuploidy, high-grade tumors can also lose all or part of chromosome 9 (Richter et al, 1997). Although almost any chromosome can be affected, aneuploidy of chromosomes 7, 9, and 17 is associated with especially aggressive tumors (Olumi et al, 1990; Waldman et al, 1991; Degtyar et al, 2004).

Because of these differing genetic imprints, it has been suggested that papillary pTa tumors could almost be considered benign and might be a completely separate disease entity in contrast to high-grade tumors (Sauter and Mihatsch, 1998; Harnden, 2007). Nevertheless, high-grade and low-grade lesions are known to coexist. UC is traditionally considered a field change disease, with tumors arising at different times and sites. Rarely, patients who initially have low-grade tumors will subsequently develop high-grade tumors, often years after the original tumors, so long-term surveillance is usually appropriate (Holmäng and Ströck, 2012).

Pathologic Characteristics by Stage and Implications for Clinical Management

Stage Ta tumors are usually low grade. Although recurrence is common, especially in the setting of multiplicity, progression is rare. However, 2.9% to 18% of Ta tumors are high grade, with an average of 6.9% (Sylvester et al, 2005). The most important risk factor for progression is grade, not stage (Millán-Rodríguez et al, 2000; Sylvester et al, 2005).

CIS is occasionally mischaracterized as “preinvasive” (Sylvester et al, 2005), but it is actually a flat, noninvasive UC that is high grade by definition and is regarded as a precursor to the development of invasive high-grade cancer.

CIS lesions are composed of severely dysplastic urothelium. Microscopically, the slide will demonstrate disorderly histology with nuclear atypia characteristic of high-grade malignancy; denudement of some or all of the mucosa as a result of loss of cellular cohesion sometimes complicates interpretation. A pathology report read as dysplasia or atypia can create confusion. Most pathologists consider mild examples of these entities to be benign. However, lesions interpreted as severe dysplasia or severe atypia are regarded as being the same entity as CIS (Epstein et al, 1998). Again, unambiguous communication between pathologist and urologist can minimize the risk for misinterpretation.

From 40% to 83% of patients with CIS will develop muscle invasion if untreated, especially if associated with papillary tumors (Althausen et al, 1976). Among patients thought to have CIS alone, up to 20% who are treated with cystectomy are found to actually contain invasion on final pathology (Farrow et al, 1976). The presence of CIS in specimens from cystectomy performed for presumed T1 tumors was associated with upstaging in 55% of patients in one series, compared with 6% upstaging in patients without CIS (Masood et al, 2004). In a series of 1500 patients, CIS was the second most important prognostic factor after grade (Millán-Rodríguez et al, 2000). Multicentricity presents another ominous characteristic of CIS (Koch and Smith, 1996). The presence of irritative voiding symptoms has been associated with diffuse disease, invasion, and a compromised prognosis, but there is no consensus on this finding in the literature (Smith et al, 1999; Sylvester et al, 2005).

TABLE 93-2 Risk of Understaging When Cystectomy Is Performed for Presumed Non–Muscle-Invasive Disease

STUDY	INSTITUTION	RISK (%) OF UNDERSTAGING
Stein et al, 2001	Southern California	39
Dutta et al, 2001	Vanderbilt University	40
Bianco et al, 2004	Wayne State University	27
Bayraktar et al, 2004	Vakif Gureba Hospital, Aksaray-Istanbul, Turkey	50
Huguet et al, 2005	Servicio de Urologia, Fundació Puigvert, Barcelona	27
Ficarra et al, 2005	University of Verona, Italy	43

T1 tumors are usually papillary and often have a narrow stalk; a nodular or sessile appearance suggests deeper invasion. Deep penetration into the lamina propria, especially if involving muscularis mucosae, increases the risk of recurrence and progression in some reports. Lymphovascular invasion (Lotan et al, 2005), pyuria (Azuma et al, 2013), and bladder neck involvement (Kobayashi et al, 2014) also increase this risk. Hydronephrosis usually indicates muscle invasion.

There is significant potential for understaging in patients with high-grade, apparently non–muscle-invasive tumors, especially those that appear to be stage T1. Many tumors are found to be more extensive than the transurethral resection (TUR) specimen indicated when patients undergo cystectomy. Stein reported that one third of patients believed to have non–muscle-invasive disease at the time of cystectomy were found to actually have muscle invasion; only half of these cases were organ confined. Metastases were already present in 8% of these patients (Freeman et al, 1995). His subsequent review noted that understaging errors from 34% to 62% have been reported (Stein et al, 2001), and a study from the Mayo Clinic before widespread use of intravesical therapy showed that 78% of patients with clinical T1 disease who underwent cystectomy had muscle invasion, with 62% having extravesical disease. Studies addressing the risk of understaging of T1 tumors are shown in Table 93-2.

Although it is likely that the patients who underwent cystectomy had more serious risk factors than those who did not, these data offer compelling evidence that the term *superficial* to describe all such lesions is misleading and would ideally be eliminated from urologic practice and the literature.

KEY POINTS: PATHOLOGY

- Malignant tumors are now classified as low grade or high grade, regardless of invasion.
- High-grade and low-grade cancers may be regarded as essentially separate diseases from genetic development, biologic behavior, and management standpoints.
- The most important risk factor for progression is grade, not stage.
- CIS is a precursor as well as a risk factor for progression, invasion, and metastasis.
- Papillary tumors with orderly cellular arrangement, minimal architectural abnormalities, and minimal nuclear atypia are designated papillary urothelial neoplasm of low malignant potential (PUNLMP).

ENDOSCOPIC SURGICAL MANAGEMENT

Procedures

When bladder cancer is identified during office-based cystoscopy, the location, number, and morphology of tumors are recorded, as is involvement of areas likely to reflect extravesical extension such as the ureteral orifices and bladder neck or prostatic urethra. Urinary cytology is obtained as a baseline and to establish the likelihood of high-grade disease. Positivity will encourage random bladder biopsy at the time of TUR, as discussed later.

Upper tract imaging is usually performed before TUR both to identify other sources of hematuria and to assess the extravesical urothelium because of the “field change” nature of UC, which can affect such tissue throughout the urinary tract. Retrograde pyelography or ureteroscopy can be planned for any upper tract abnormalities identified. Expert consensus is that patients with solitary or limited low-grade Ta lesions do not need imaging unless they have concomitant hematuria, owing to the very low risk of extravesical disease (Goessl et al, 1997; Davis et al, 2012).

Transurethral resection of bladder tumor (TURBT) under regional or general anesthesia is the initial treatment for visible lesions and is performed to (1) remove all visible tumors and (2) provide specimens for pathologic examination to accurately determine stage and grade. Bimanual examination of the bladder is often performed with the patient under anesthesia before preparation and draping unless the tumor is clearly small and noninvasive, and is repeated after resection. Fixation or persistence of a palpable mass after resection suggests locally advanced disease, although the additional value of this maneuver in the era of modern imaging appears limited and may even be misleading (Ploeg et al, 2012). An increase in abdominal girth or fullness after resection suggests intraperitoneal perforation.

Complete visualization to plan the resection is facilitated by either the flexible cystoscope or preferably the 70-degree rigid rod lens, which allows maintenance of the anatomic relationships. Resection is performed using a 12- or 30-degree lens placed through a resectoscope sheath because this deflection allows visualization of the loop placed at this location. Continuous irrigation with the bladder filled only enough to visualize its contents minimizes bladder wall movement and lessens thinning of the detrusor through overdistention, which should reduce the risk of perforation (Koch and Smith, 1996). Video TUR allows magnification, facilitates resident teaching, allows documentation of findings, and reduces the risk of body fluid exposure to the surgeon (Manoharan and Soloway, 2005; Nieder et al, 2005). Resection is performed piecemeal, delaying transection of any stalk until most tumor has been resected, to maintain countertraction. Friable, low-grade tumors can often be removed without the use of electrical energy because the nonpowered cutting loop will break off many low-grade tumors. This minimizes the chance of bladder perforation and unnecessary cautery damage or loss of specimens. Higher-grade, more solid tumors and the base of all tumors require the use of cutting current; cautery yields hemostasis once the entire tumor has been resected. Lifting the tumor edge away from detrusor lessens the chance of perforation (Holzbeierlein and Smith, 2000). Repeated slow fulguration may complicate the ability of the pathologist to determine grade or invasion status. There appears to be variability in completeness of resection among surgeons. In patients with multiple tumors who had adjuvant treatment, recurrence rates varied from 7.4% to 45.8% depending on the surgeon (Brausi et al, 2002).

After all visible tumor has been resected, an additional pass of the cutting loop or a cold-cup biopsy can be obtained to send to pathology separately to determine the presence of muscle invasion of the tumor base. A chip evacuator gathers the specimen. Final confirmation of hemostasis in the presence of minimal irrigation after all chips have been removed through vigorous irrigation is helpful.

Traditionally, TUR has been performed in sterile water because saline solutions conduct electricity and disperse energy from the

monopolar cautery cutting loop. Glycine is more expensive, and there is no evidence of its benefit in this setting compared with water (Holzbeierlein and Smith, 2000). Introduction of bipolar electroresection is reported to allow TUR in saline and to minimize the risk of the obturator reflex, which can predispose to bladder perforation (Shiozawa et al, 2002; Miki et al, 2003). The use of general anesthesia with muscle-paralyzing agents also prevents obturator reflex, although I find this rarely necessary. This can also be accomplished by direct injection of 20 to 30 mL of local anesthetic (lidocaine) into the obturator nerve and its canal, but few centers have experience with this (Khorrami et al, 2010).

Resection of diverticular tumors presents significant risk of bladder wall perforation, and accurate staging is difficult to achieve in this circumstance because the underlying detrusor is absent. Invasion beyond the diverticular lamina propria immediately involves perivesical fat (stage T3a by definition). Resection in diverticula almost inevitably leads to perforation. **Low-grade diverticular tumors are best treated with a combination of resection and fulguration of the base.** Conservative resection can be followed with subsequent repeat resection if the final pathologic interpretation is high grade. High-grade tumors require adequate sampling of the tumor base, often including perivesical fat, despite the near certainty of bladder perforation. An indwelling catheter usually allows healing within a few days. **Partial or radical cystectomy should be strongly considered for high-grade diverticular lesions.**

Anterior wall tumors and tumors at the dome in patients with large bladders can be difficult to reach. Minimal bladder filling combined with manual compression of the lower abdominal wall to bring the tumor toward the resectoscope facilitates removal. Modern resectoscopes are long enough to reach the entirety of most bladders; creation of a temporary perineal urethrostomy offers deeper access but is rarely necessary except in the obese patient with an inaccessible tumor. Digital manipulation through the rectum or vagina can occasionally facilitate resection.

Care must be taken during resection near the ureteral orifice to prevent obstruction from scarring after fulguration. **Pure cutting current causes minimal scarring and may be safely performed, including resection of the orifice if necessary.** Resection of the intramural ureter can sometimes lead to complete eradication of the tumor but risks reflux of malignant cells. The clinical implications of this are unclear (Palou et al, 1992).

Alternatively, **small tumors may be resected using the cold-cup biopsy forceps alone.** This is especially helpful in elderly women, who are predisposed to perforation owing to their thin-walled bladders. If perforation occurs, the cup causes a smaller hole than does the cutting loop. A Bugbee electrode facilitates hemostasis. **A successful cauterization method involves placing the Bugbee electrode inside the biopsy site with the bladder under minimal distention.** When the electrode touches the cut surface of the biopsy crater, the electrical energy will cause the mucosa to contract around the electrode unless the bladder is full. Light irrigation clears the area of blood and vaporization bubbles created during fulguration. Visualizing a small (1 to 2 mm) ring of white coagulation confirms hemostasis and yields less damage to the bladder than that occurring when the biopsy area is "painted" with cautery. Removing the electrode from the site before discontinuing the energy current lessens the chance of pulling the fresh clot off as the Bugbee electrode separates from the urothelium.

If a tumor appears to be muscle invasive, biopsies of the borders and base to establish invasion may be performed in lieu of complete resection, because cystectomy will likely follow based on confirmatory biopsies. Failure to demonstrate invasion necessitates repeat resection unless the decision is made to proceed to cystectomy based on factors other than muscle invasion.

The necessity of obtaining detrusor muscle in the surgical specimen is widely taught but not established in benefit. For example, the potential for muscle invasion for low-grade disease is essentially nonexistent, so a transmural biopsy offers little potential benefit compared with the risk of bladder perforation incurred. If a grading miscalculation occurs, a repeat TUR with intentional procurement

of underlying detrusor is routine practice as described later and is included in American Urological Association (AUA) guidelines (Hall et al, 2007).

Complications of Transurethral Resection of Bladder Tumor and Bladder Biopsy

Minor bleeding and irritative symptoms are common side effects in the immediate postoperative period. The major complications of uncontrolled hematuria and clinical bladder perforation occur in fewer than 5% of cases, although a majority of patients will exhibit contrast agent extravasation indicative of minor perforation if cystography is performed. The incidence of perforation can be reduced by attention to technical details, avoiding overdistention of the bladder, and using anesthetic paralysis during the resection of significant lateral wall lesions to lessen an obturator reflex response. Moreover, large, bulky tumors and those that appear to be muscle invasive are often best resected in a staged manner because it is believed that repeat resection can more safely remove residual tumor if indicated.

The vast majority of perforations are extraperitoneal, but intraperitoneal rupture is possible when tumors are resected at the dome (Collado et al, 2000). The risk of tumor seeding from perforation appears to be low (Balbay et al, 2005). Anecdotal reports have identified extravesical recurrences after perforation, theoretically caused by seeding (Mydlo et al, 1999). It has been suggested that the risk of tumor seeding is higher in patients who undergo surgical repair, but this may be related to patient selection because only serious intraperitoneal perforations are likely to be managed in this manner (Mydlo et al, 1999; Skolarikos et al, 2005).

Management of extraperitoneal perforation by prolonged urethral catheter drainage is usually possible. Intraperitoneal perforation is less likely to close spontaneously and usually requires open or laparoscopic surgical repair. Decisions for surgical correction should be made on the basis of the extent of the perforation and the clinical status of the patient.

TUR syndrome from fluid absorption is uncommon and managed in the same manner as during transurethral resection of the prostate (TURP).

As long as resection of the ureteral orifice is performed with pure cutting current, scarring is minimal and obstruction unlikely. Cystoscopy to visualize efflux, which is occasionally aided by intravenous administration of indigo carmine or methylene blue or retrograde ureteropyelography, can determine presence or absence of obstruction. If fluorescence cystoscopy is in use as described later, the urine jet will fluoresce brightly as well. If the orifice is resected or cautery is used nearby, renal ultrasonography in the postoperative period can identify asymptomatic obstruction. Balloon dilation of the orifice or endoscopic incision can relieve obstruction, but failure to respond will rarely necessitate reimplantation (Chang et al, 1989).

Repeat Transurethral Resection of Bladder Tumor

Complete tumor removal is not always possible, whether as a result of excessive tumor volume, anatomic inaccessibility, medical instability requiring premature cessation, or risk of perforation. However, even in the absence of these circumstances **repeat TUR is often indicated if high-grade tumor is identified.** When repeat TUR is performed within several days to several weeks of the original resection, residual tumor is identified at the site of the initial resection at least 40% of the time (Klan et al, 1991; Mersdorf et al, 1998; Vogeli et al, 1998). In a review, Miladi and coworkers (2003) found that a second TURBT detected residual tumor in 26% to 83% of patients and corrected clinical staging errors in half of those patients. The potential for understaging high-risk disease ranged from 18% to 37% (Amling et al, 1994).

Repeat TURBT is usually appropriate in the evaluation of T1 tumors because a repeat TUR can demonstrate worse prognostic findings in up to 25% of specimens (Schwaibold et al, 2000). This

is especially likely if no muscle is identified on initial pathology, which can occur in almost half of cases. The Vanderbilt University group reported a 64% risk of understaging T1 lesions when muscle was absent, compared with 30% when muscle was present in the specimen (Dutta et al, 2001). Herr (1999) reported that a second resection changed treatment in one third of patients. It is important to note that survival was 63% in patients who underwent a second TURBT versus 40% for those who did not in a German observational study (Grimm et al, 2003), and recurrences appear to be lower after repeat TUR (Sfakianos et al, 2014). The efficacy of bacille Calmette-Guérin (BCG) in preventing progression appears to be higher in patients with high-grade papillary tumors and CIS if a restaging TURBT was performed before instillation of BCG (Herr, 2005).

Repeat resection is helpful in the setting of a second opinion unless clear evidence of muscle invasion is identified on the initial resection, especially if the outside pathology slides are not available for review. Alternatively, subspecialty pathologic reinterpretation at the time of second opinion can yield information potentially leading to a change in management in almost one third of patients (Lee et al, 2010).

The consensus is that patients with pT1 and many high-grade Ta tumors merit repeat resection. There is no consensus on timing, but most authors recommend 1 to 6 weeks after the initial resection (Nieder et al, 2005).

Role of Random or Additional Biopsies

Biopsies of any suspicious areas are an important part of a complete evaluation. Cold-cup biopsies may not provide as much information regarding muscular invasion but provide tissue sampling without cautery artifact that can interfere with pathologic interpretation (Soloway et al, 1978; Smith, 1986).

The use of random biopsies to identify CIS in otherwise normal-appearing mucosa remains controversial. May and colleagues (2003) performed random biopsies in high-risk patients and found that the results were positive in 12.4% and altered treatment in 7%, including 14 of 1033 patients in whom the only positive tissue was in the random biopsy specimen, not the primary resected tumor. However, even when velvety red patches were sampled, only 11.9% of biopsy specimens were positive in one report (Swinin et al, 2004). A European Organisation for Research and Treatment of Cancer (EORTC) retrospective review found that 10% of random biopsy specimens were positive (3.5% CIS) and concluded that such biopsies were not warranted (van der Meijden et al, 1999). Fujimoto and colleagues (2003) prospectively evaluated the role of random biopsies of normal-appearing urothelium and found cancer in only 8 of 100 biopsy samples, 5 of which were CIS. They concluded that random biopsies are indicated only in the setting of multiple tumors or positive cytology. The current consensus is that random biopsies are not indicated in low-risk patients (i.e., those with low-grade papillary tumors and negative cytology), but there remains no consensus with regard to patients with high-grade disease, and most urologists perform random biopsies in this setting.

Prostatic urethral biopsy using the cutting loop may be performed, especially if neobladder creation is anticipated for high-risk disease, but bleeding may be more common (Holzbeierlein and Smith, 2000). The additional value of the information obtained from cold-cup and urethral biopsies must be weighed against the theoretic risk that biopsies provide an exposed bed to aid tumor implantation (Kiemeneij et al, 1994; Yamada et al, 1996). Traditional teaching is that TURP and TURBT of a low-grade bladder tumor may be performed at the same setting but that resection of a high-grade bladder tumor should not be performed coincident to TURP to avoid tumor seeding and possible intravasation of tumor cells likely to metastasize. Despite anecdotal reports of low-grade tumors implanting in the prostatic urethra after simultaneous resection, this risk appears to be small (Tsivian et al, 2003).

Laser Therapy

Laser coagulation allows minimally invasive ablation of tumors up to 2.5 cm in size. The neodymium:yttrium-aluminum-garnet (Nd:YAG) laser has the best properties for use in bladder cancer. Lesions can be coagulated until nonviable through protein denaturation using a straight or 90-degree noncontact "free beam" laser using power output of up to 60 W. The most significant complication of laser therapy is forward scatter of laser energy to adjacent structures, resulting in perforation of a hollow, viscous organ such as overlying bowel. This is rare but most commonly occurs with the Nd:YAG laser because of its deeper tissue penetration than with holmium(Ho):YAG and potassium titanyl phosphate (KTP) lasers (Smith, 1986). Unless higher energy is necessary for a very large tumor, limiting energy to 35 W precludes exceeding 60°C on the outer bladder wall, minimizing the risk of perforation (Hofstetter et al, 1994). The most efficient delivery appears to be an end-fire noncontact fiber with a 5- to 15-degree angle of divergence, which allows variable penetration depth up to 5 mm (Smith and Landau, 1989; Holzbeierlein and Smith, 2000). Treatment should be under direct visualization and should discontinue as soon as protein denaturation is evident by the white appearance of the treated tissue. Persistence after this occurs risks extravesical injury.

Laser therapy can be more expensive than resection owing to the cost of laser fibers, but bleeding is negligible and there is no risk of obturator reflex. Small lesions can be treated easily using intravesical anesthesia. Because there is no tissue available for pathologic inspection, the optimal candidate for laser therapy is the patient with recurrent, low-grade lesions whose biology is already known. Additional information regarding tumor grade may be obtained with a cold-cup biopsy if necessary. Some reports suggest lower recurrence rates using laser compared with TURBT, but this remains inconclusive (Smith et al, 1983; Malloy et al, 1984; Beisland and Seland, 1986; Smith, 1986; Beer et al, 1989).

Office-Based Endoscopic Management

Many patients with small (typically <0.5 mL, but up to 1 cm diameter in experienced hands), low-grade recurrences can be managed safely in the office setting with use of diathermy or laser ablation (Donat et al, 2004). Instillation of viscous or injectable 1% to 2% lidocaine through a catheter and a dwelling time of 15 to 30 minutes yields satisfactory mucosal analgesia, although pain with fulguration of 1- to 5-mm tumors is often acceptable without analgesia. A prior tissue diagnosis and a negative cytology for the initial tumor occurrence are mandatory to determine whether the tumor is of high or low grade.

In addition, many small, low-grade tumors can be safely observed until they exhibit significant growth because of the minimal risk of progression (Soloway et al, 2003; Pruthi et al, 2008).

Fluorescence Cystoscopy and Narrow Band Imaging

Endoscopically, urologists can suspect malignancy only on the basis of the presence of visible changes such as tumors or "red spots." As noted, random biopsy of normal-appearing areas occasionally detects unsuspected malignancy, usually CIS. Conversely, a multicenter study found that 37% of the biopsies performed on the basis of suspicious endoscopic findings resulted in a false-negative biopsy, emphasizing the subjectivity and attendant false-positive and false-negative rates of cystoscopy (Riedl et al, 2001). The imperfect sensitivity of cystoscopy potentially explains the high rate of cancer recurrence soon after complete removal of all visible tumors (tumor cell implantation also contributing, as described earlier). It is likely that cancer was already present but not visible at the time of resection and simply became visible at follow-up when it became morphologically abnormal enough to differentiate from adjacent normal urothelium.

Photoactive porphyrins accumulate preferentially in neoplastic tissue. Under blue light they emit red fluorescence, which can help in the diagnosis of indiscernible malignant lesions. Intravesical application of 5-aminolevulinic acid (5-ALA), a precursor of photoactive porphyrin, avoids residual systemic photosensitization (Lange et al, 1999).

When this technology is used, both small papillary tumors and almost one third more cases of CIS overlooked on cystoscopy are identified (Jichlinski et al, 2003; Schmidbauer et al, 2004; Fradet et al, 2007). Of all tumors, 96% were detected with hexaminolevulinate (HAL) imaging compared with 77% with standard cystoscopy. Detection was improved for CIS (95% vs. 68%), and papillary tumors (96% vs. 85%) (Jocham et al, 2005). The clinical impact of improved tumor detection seems intuitive, and prospective evidence has shown that this decreases recurrence rates in patients who undergo HAL fluorescence cystoscopy compared with controls (Filbeck et al, 2003; Denzinger et al, 2007; Grossman, 2007; Rink et al, 2013). This impact appears to persist for at least 4 years. There may be an impact on progression, although the study was underpowered to prove this trend (Stenzl et al, 2010) (Figs. 93-6 and 93-7).

Narrow band imaging (NBI) is an optical image enhancement technology intended to improve the visibility of blood vessels

inherent to neoplastic processes. NBI light is composed of two specific wavelengths that are absorbed by hemoglobin; 415-nm light penetrates only the superficial mucosal layers, whereas 540-nm light penetrates more deeply. The combination allows improved visualization of tumors. The clinical impact of this remains under investigation, and no studies have been performed to date regarding recurrence or progression (Liu et al, 2012).

KEY POINTS: ENDOSCOPIC SURGICAL MANAGEMENT

- TURBT is performed both to remove all visible tumors and to provide specimens for pathologic examination to determine stage and grade.
- Repeat resection within 1 to 6 weeks is usually indicated in patients with high-grade disease, especially if no muscle was present in the initial TURBT.
- All suspicious lesions should be sampled, but random biopsies are not required in low-risk patients.
- Office-based fulguration and observation may be applied to certain low-risk patients.
- Fluorescence cystoscopy with 5-ALA derivatives improves the ability to visualize inconspicuous tumors and reduces recurrence rates after TUR.

PERIOPERATIVE INTRAVESICAL THERAPY TO PREVENT TUMOR IMPLANTATION

It is believed that tumor cell implantation immediately after resection is responsible for many early recurrences, and this has been used to explain the observation that initial tumors are most commonly found on the floor and lower sidewalls of the bladder, whereas recurrences are often located near the dome as a result of “flotation” (Heney et al, 1981). Thus, intravesical chemotherapy to kill such cells before implantation has been used for decades (Zincke et al, 1983; Klan et al, 1991).

Mitomycin C (MMC) appears to be the most effective adjuvant intravesical chemotherapeutic agent perioperatively, although epirubicin is used in Europe and direct comparative studies are lacking (Witjes and Hendricksen, 2008). Consistent with its proposed mechanism of action to prevent tumor cell implantation, a single dose administered within 6 hours lessens recurrence rates, whereas a dose 24 hours later does not (Isaka et al, 1992; Oosterlinck et al, 1993; Sekine et al, 1994; Solsona et al, 1999; Duque and Loughlin, 2000), and maintenance therapy does not reduce the risk further (Bouffieux et al, 1995; Tolley et al, 1996). Nevertheless, level 1 data demonstrate clearly that single-dose MMC or epirubicin immediately after resection reduces tumor recurrence, particularly for the initial presentation of a solitary papillary low-grade tumor (Box 93-1).

A meta-analysis found that low-risk patients at a median follow-up of 3.4 years experience a drop in the odds of recurrence from 48.4% to 36.7%. Patients with multiple tumors experience a 56% reduction in the odds of recurrence. MMC, epirubicin, and pirarubicin all significantly lessened the recurrence of both single and multiple tumors. Thiotepa did not show the same benefit, but data were limited and some studies used dilute strengths (Sylvester et al, 2004). The number needed to treat (NNT) to prevent one recurrence in the meta-analysis was 8.5, so some authors have suggested that intravesical chemotherapy reduces overall cost of care by reducing the need for secondary resections. However, subsequent studies have shown that the tumors prevented are primarily smaller tumors that are often treated in the office or ambulatory surgery setting (Berrum-Svennung et al, 2008). In addition, the benefit appears limited to patients with low risk of recurrence (Gudjonsson et al, 2009), so the economic impact regarding recurrences remains controversial if recurrences are treated in any manner other than inpatient care (Rao and Jones, 2009; Lee et al, 2012).

BOX 93-1 Successful Perioperative Administration of Intravesical Chemotherapy

1. Include intent to administer perioperative chemotherapy (and agent) on actual operative schedule.
2. Contact pharmacy before surgery to have medication available. A written prescription may be required.
3. After resection, confirm absence of clinical perforation. Place three-way catheter into bladder while patient is still in operating room. Attach inflow port to saline infusion bag and clamp inflow.
4. Administer chemotherapeutic agent through catheter outflow port in recovery room within 6 hours of operation, and clamp outflow tubing with hemostat to allow retention.
5. Give order for outflow tubing to be opened 1 hour after administration and for irrigation, to be opened to gravity drainage for next 30 to 60 minutes.
6. Remove Foley catheter and discard in biohazard container.
7. Wear gloves.

Modified from O'Donnell MA. Practical applications of intravesical chemotherapy and immunotherapy in high-risk patients with superficial bladder cancer. *Urol Clin North Am* 2005;32:121–31.

The use of perioperative intravesical therapy is widespread in Europe but has achieved limited adoption in the United States (Madeb et al, 2009) potentially because of the cost, complexity, and potential for side effects, combined with the fact that it has not been shown to have adequate impact for recurrent, multiple, or high-grade tumors (Sylvester et al, 2004).

Although local irritative symptoms are the most common complications of postoperative instillation, serious sequelae and rare deaths have occurred, especially in patients with perforation during resection (Oddens et al, 2004). Other reported conditions associated with intravesical chemotherapy (with perioperative or multidose regimens) include chemical cystitis, cutaneous desquamation, decreased bladder capacity as a result of contractures, calcified eschars, and complications or added difficulty of subsequent cystectomy (Doherty et al, 1999; Cliff et al, 2000; Nieuwenhuijzen et al, 2003; Oddens et al, 2004; Shapiro et al, 2006). Chemotherapy should be withheld in patients with extensive resection or when there is concern about perforation.

BCG can never be safely administered immediately after TUR because the risk of bacterial sepsis and death is high.

KEY POINTS: PERIOPERATIVE INTRAVESICAL THERAPY TO PREVENT TUMOR IMPLANTATION

- Single-dose intravesical chemotherapy administered within 6 hours of resection reduces recurrence of low-risk tumors, with significant impact in the setting of initial presentation of solitary low-grade papillary tumors.
- The incremental benefit in patients with recurrent or multiple tumors is limited.
- No benefit has been found in patients with high-grade disease.

IMMUNOTHERAPY**Bacille Calmette-Guérin**

BCG is an attenuated mycobacterium developed as a vaccine for tuberculosis that has demonstrated antitumor activity in several

different cancers including UC (Morales et al, 1976). The original regimen described by Morales included a percutaneous dose, which was discontinued after success with a similar intravesical regimen by Brosman (1982).

BCG powdered vaccine is reconstituted with 50 mL of saline and should be administered through a urethral catheter under gravity. Treatments are typically begun 2 to 4 weeks after tumor resection, allowing time for re-epithelialization, which minimizes the potential for intravasation of live bacteria (Lamm et al, 1992). For the same reason, a urinalysis is usually performed immediately before instillation to further confirm absence of infection or significant bleeding to decrease the likelihood of systemic uptake of BCG. In the event of a traumatic catheterization, the treatment should be delayed for several days to 1 week, depending on the extent of injury. Active urinary tract infection is often considered an indication to delay treatment until it has been managed, but recent publications question the need to avoid BCG in the presence of asymptomatic bacteriuria (Herr, 2012). After instillation, the patient should retain the solution for at least 2 hours. Some clinicians have advocated that the patient turn from side to side to bathe the entire urothelium, but there is no scientific support for this practice. Fluid, diuretic, and caffeine restriction before instillation limits dilution of the agent by urine and facilitates adequate retention of the agent for 2 hours (Lamm et al, 2000b). Patients are usually instructed to clean the toilet with bleach, although there is no demonstrable risk of close contact infection.

Mechanism of Action

Intravesical immunotherapy results in a massive local immune response characterized by induced expression of cytokines in the urine and bladder wall and by an influx of granulocytes and mononuclear and dendritic cells (Shen et al, 2008). The initial step appears to be direct binding to fibronectin within the bladder wall, subsequently leading to direct stimulation of cell-based immunologic response and an antiangiogenic state. Numerous cytokines involved in the initiation or maintenance of inflammatory processes including tumor necrosis factor- α (TNF- α), granulocyte-macrophage colony-stimulating factor (GM-CSF), interferon- γ (IFN- γ), and interleukin-1 (IL-1), IL-2, IL-5, IL-6, IL-8, IL-10, IL-12, and IL-18 have been detected in the urine of patients treated with intravesical BCG and other immunostimulatory agents. The observed pattern of cytokine induction with preferential upregulation of IFN- γ , IL-2, and IL-12 reflects induction of a T-helper type-1 (Th1) response. This immunologic response activates cell-mediated cytotoxic mechanisms that are believed to underlie the efficacy of BCG and other agents in the prevention of recurrence and progression (Bohle and Brandau, 2003). BCG may concomitantly stimulate IL-10, resulting in the suppressive Th2 response. Overall, response to intravesical immunotherapy may be limited if a patient has an immunosuppressive disease or by advanced age (Joudi et al, 2006a, 2006b).

Bacille Calmette-Guérin Treatment of Carcinoma in Situ

American urologists use BCG by a 2:1 margin compared with intravesical adjuvant or maintenance chemotherapy (e.g., doxorubicin hydrochloride [Adriamycin], gemcitabine, thiotepa), whereas European urologists favor chemotherapy. BCG is approved for this indication by the U.S. Food and Drug Administration (FDA). Before the adoption of BCG intravesical therapy, CIS reportedly progressed at an average rate of 7% per year (Zinke et al, 1985). The initial tumor-free response rate is as high as 84% (Brosman, 1982; De Jager et al, 1991; Hudson and Herr, 1995; Lamm et al, 2000a, 2000b, 2000c). Approximately 50% of patients experience a durable response for a median period of 4 years. Over a 10-year period, approximately 30% of patients remain free of tumor progression or recurrence, so close follow-up is mandatory. The majority of these occur within the first 5 years (Herr et al, 1992). Herr and coworkers (1989) reported progression in

19% of initial responders at 5 years but found the rate to be 95% in nonresponders—findings confirmed by other investigators (Coplen et al, 1990; Harland et al, 1992). The AUA guidelines panel supported BCG as the preferred initial treatment option for CIS (Hall et al, 2007).

BCG has gained a preeminent role in North America on the basis of higher efficacy reports compared with intravesical chemotherapy, despite greater morbidity than chemotherapy (O'Donnell, 2007). In more than 600 patients, there was a 68% complete response rate to BCG and a 49% complete response rate to chemotherapy. In responders, 68% of patients treated with BCG remained free of disease as compared with 47% of patients receiving chemotherapy, on the basis of a median follow-up of 3.75 years. The overall disease-free rates were 51% and 27%, respectively (Sylvester et al, 2005).

Bacille Calmette-Guérin Treatment of Residual Tumor

Intravesical BCG can effectively treat residual papillary lesions but should not be used as a substitute for surgical resection. Investigators have demonstrated a nearly 60% response by residual tumor with intravesical BCG alone (Brosman, 1982; Schellhammer et al, 1986; Coplen et al, 1990).

Carcinoma of the mucosa or the superficial ducts of the prostate can be adequately treated by BCG with a 50% tumor-free rate. A limited TURP or fulguration can be effective in decreasing tumor burden and facilitating exposure of the prostate surface to BCG administration (Bretton et al, 1990; Schellhammer et al, 1995).

Bacille Calmette-Guérin Prophylaxis to Prevent Recurrence

Early single-center studies demonstrated an advantage in decreased tumor recurrence of approximately 30% when a 6-week course of BCG was administered after recovery from TURBT (Brosman, 1982; Morales et al, 1992). In several larger series, tumor recurrence after TURBT was reduced by 20% to 65%, for an average of approximately 40% (Pagano et al, 1991a, 1991b; Herr et al, 1992; Melekos et al, 1993; Krege et al, 1996). A meta-analysis of 2000 patients with Ta, T1, and/or CIS disease found that patients receiving maintenance BCG had a statistically decreased rate of recurrence compared with those receiving induction therapy alone (Han and Pan, 2006). A subsequent reevaluation of the published data concluded that 3 years of maintenance therapy was supported by the literature but that patients with intermediate-risk disease may be equally managed with 1 year of maintenance (Ehdaie et al, 2013).

The efficacy of BCG after TURBT for high-risk papillary disease has been demonstrated in several series of T1 lesions, with recurrence rates of 16% to 40% and progression rates of 4.4% to 40%, a substantial improvement compared with TUR alone (Cookson and Sarosdy, 1992; Pansadoro et al, 1995; Herr, 1997; Jimenez-Cruz et al, 1997; Gohji et al, 1999; Hurler et al, 1999a, 1999b). Tumor multiplicity and associated CIS were associated with increased risk of progression. Substaging lesions on the basis of the presence or absence of muscularis mucosae invasion in a series of 49 patients did not improve prediction of recurrence (69% vs. 65%) or progression (22% vs. 29%) after BCG therapy (Kondylis et al, 2000).

Impact of Bacille Calmette-Guérin on Progression

Although reports of the impact of BCG on tumor recurrence are compelling, the greater need is the potential for impact on progression. In 403 patients with CIS, BCG reduced the risk of progression by 35% compared with intravesical chemotherapy (Sylvester et al, 2002).

In a randomized trial of 86 patients with high-risk superficial disease, Herr and colleagues (1988) demonstrated a greater delay in interval progression for BCG patients versus TUR controls. In addition, the cystectomy rate was significantly decreased for CIS patients treated with BCG (11% vs. 55% for controls), as was the time to cystectomy. However, only 27% of patients were alive with

an intact functioning bladder after follow-up over 10 to 15 years, so this apparent advantage is temporary in many cases (Cookson et al, 1997). Available data suggest that BCG can delay progression of high-risk bladder cancer, yet the long-term survival advantage is not fully defined.

Nevertheless, two meta-analyses have concluded that BCG reduces the risk of progression. Progression at 2.5 years' median follow-up was reduced by 27% (9.8% for BCG vs. 13.8% for non-BCG) in one (Sylvester et al, 2002) and by 23% (7.7% for BCG vs. 9.4% for MMC) at 26-month median follow-up in another analysis (Bohle and Bock, 2004). In both cases the superior results with BCG were seen only in trials using BCG maintenance therapy. In contrast, no chemotherapy trials have achieved a significant reduction in progression (Grossman et al, 2008).

The AUA guidelines panel concluded that BCG appeared likely to reduce progression (Hall et al, 2007).

Determining Optimum Bacille Calmette-Guérin Treatment Schedule

The optimal treatment schedule and dose for BCG have not been established (Herr et al, 2011). Morales wrote in the reply to an editorial comment to his landmark article, "This regimen is arbitrary, and may be modified in the future as additional data become available" (Morales et al, 1976). In reality, several studies suggest that a 6-week induction course alone is insufficient to obtain an optimal response in many patients and that maintenance therapy is requisite (Lamm et al, 2000a, 2000b, 2000c; Palou et al, 2001).

One of the enduring urban myths in urology is the story of the initial work of Dr. Alvaro Morales with BCG. Although the rumor is usually stated that he chose the dosage regimen based on the fact that the drug is shipped in a "six-pack," he relates that there is more to the story: "A contemporary abstract had indicated that BCG was ineffective for bladder cancer. However, from our experience and that of others, we knew that at least a 3-week period of immunizations was needed for mounting a delayed hypersensitivity reaction. The intradermal administration provided not only assurance of an enhanced systemic recognition, but also an inexpensive and readily available marker of immune competence. To this day, I remain convinced that eliminating the simultaneous transdermal administration is very convenient for patients and physicians but is not as effective. It was our impression that the skin reactions reached by weeks 4 to 5 were not further enhanced by more BCG. The Frappier labs provided us with boxes of six vials. We thus—for better or worse—decided to stop treatment at 6 weeks, assuming that what was seen on the skin was occurring on the bladder mucosa. Fortunately, that turned out to be true. Bohle and others reported years later that 6 weeks were ideal for maximum response to BCG, although we now know that maintenance dosing enhances response even further."

The average additional response to a second induction course is 25% in those patients treated for prophylaxis and 30% in CIS patients (Haaff et al, 1986; Kavoussi et al, 1988; Bretton et al, 1990; Coplen et al, 1990; Sylvester et al, 2002; Bohle and Bock, 2004). However, additional courses of BCG to treat refractory patients after a second 6-week course are accompanied by a significant risk of tumor progression in 20% to 50% of patients (Nadler et al, 1994). Catalona and colleagues (1987) reported roughly a 7% actuarial risk of progression with every additional course of BCG therapy. Response to BCG at 6 months can be used as a predictor of prognosis, with the number of patients developing progressive disease being significantly higher among nonresponders (Orsola et al, 1998).

The Southwest Oncology Group (SWOG) reported the most significant impact of maintenance therapy. Patients received a 6-week induction course followed by three weekly instillations at 3 and 6 months and every 6 months thereafter for 3 years. Estimated median recurrence-free survival was 76.8 months in the maintenance arm and 35.7 months in the control arm ($P = .0001$). Average recurrence-free survival was 111.5 months in the

control arm and was not able to be estimated in the maintenance arm ($P = .04$). Overall 5-year survival was 78% in the control arm and 83% in the maintenance arm. No toxicities above grade 3 were observed, yet **only 16% of patients tolerated the full dose-schedule regimen**. Two thirds of the patients who stopped BCG because of side effects did so in the first 6 months, suggesting that the side effects do not increase appreciably with additional time on therapy. An interpretation that the intended full course of maintenance therapy cannot be accomplished in most patients because of side effects is misleading. **Owing to the fact that the treatment group fared better despite most patients having failed to complete the full course of therapy, the maximum benefit may have been achieved earlier. Shorter maintenance schedules and reduced dosages may accomplish the same results with less toxicity** (Lamm et al, 2000a).

For high-grade T1 lesions or CIS, maintenance therapy has proven superior in multiple studies (Palou et al, 2001). **The determination of whether the optimal treatment schedule should be as described in the SWOG study, monthly, or on some other schedule remains undefined, and optimal duration of a monthly maintenance schedule, if chosen, is unknown** (Lamm et al, 2000a, 2000b, 2000c; O'Donnell, 2005).

Several investigators have evaluated the potential for BCG dose reduction (Morales et al, 1992; Melekos et al, 1993; Martinez-Pineiro et al, 1995; Pagano et al, 1995). In general, a decrease in toxicity with no statistical difference in efficacy has been noted in small series (Pagano et al, 1991b; Mack and Frick, 1995; Hurler et al, 1996), although multifocal and high-grade tumors may respond better to full dosage (Martinez-Pineiro et al, 2002). Some studies have shown an upregulation of the Th1 response with a lower dose of BCG. Lengthening of the instillation interval may decrease side effects without loss of efficacy (Bassi et al, 2000). Studies in Europe, where BCG inoculation for tuberculosis is more common than in North America, suggest that the dose may be safely reduced by half (Martinez-Pineiro et al, 2002). The difference in response to doing so in immunologically naive North Americans is unknown, but Morales and colleagues (1992) found a significant decrease in response rates (67% vs. 37%), especially for patients with CIS in combination with papillary tumors treated with the reduced dose.

Antibiotic therapy may have a beneficial effect in treating or preventing systemic side effects of BCG therapy, yet it may also inhibit the effectiveness of BCG therapy if it is given routinely for urinary tract prophylaxis during a course of BCG therapy (Durek et al, 1999a, 1999b). **Quinolones in particular may affect the viability of BCG and should be avoided if possible during the course of BCG treatments** (Durek et al, 1999b) (Boxes 93-2 and 93-3).

Interferon

IFNs are glycoproteins produced in response to antigenic stimuli. These agents have multiple antitumor activities including inhibition of nucleotide synthesis; upregulation of tumor antigens, anti-angiogenic properties; and stimulation of cytokine release with enhanced T- and B-cell activation, as well as enhanced natural killer cell activity (Naitoh et al, 1999). Among several subtypes, IFN- α has been the most extensively studied. It is most active in doses of at least 100 million units, although optimal dose and administration schedule have yet to be determined (Torti et al, 1988; Belldgrun et al, 1998).

IFN as a solitary agent is more expensive and less effective than BCG or intravesical chemotherapy in eradicating residual disease, preventing recurrence of papillary disease, and treating CIS (20% to 43% complete response). Its long-term efficacy for CIS is less than 15% (Belldgrun et al, 1998). A randomized trial demonstrated CIS responses from 5% at low doses (10 million units) to as high as 43% at high doses (100 million units) (Torti et al, 1988). As a prophylactic agent, IFN alone demonstrated recurrence rates that were inferior in general to those of BCG alone (from 60% to 16%) (Glashan, 1990; Kalble et al, 1994). It has demonstrated limited

BOX 93-2 Contraindications to Bacillus Calmette-Guérin (BCG) Therapy

ABSOLUTE CONTRAINDICATIONS

Immunosuppressed and immunocompromised patients*
Immediately after transurethral resection on the basis of the risk of intravasation and septic death
Personal history of BCG sepsis
Gross hematuria (intravasation risk)
Traumatic catheterization (intravasation risk)
Total incontinence (patient will not retain agent)

RELATIVE CONTRAINDICATIONS

Urinary tract infection (intravasation risk)
Liver disease (precludes treatment with isoniazid if sepsis occurs)
Personal history of tuberculosis (risk theorized but unknown)
Poor overall performance status
Advanced age

NO OR INSUFFICIENT DATA ON POTENTIAL CONTRAINDICATIONS

Patients with prosthetic materials have not been shown to have increased risk of infectious or other complications in limited literature (Rosevear et al, 2010)
Ureteral reflux
Anti-tumor necrosis factor medications (theoretically predispose to BCG sepsis)

*Recent small series suggest this may not be an absolute contraindication (Herr, 2012).

From Ehlers S. Why does tumor necrosis factor targeted therapy reactivate tuberculosis? *J Rheumatol* (Suppl) 2005;74:35-9.

activity against T1 tumors (Malmstrom, 2001). However, it can occasionally be effective in patients in whom BCG has failed (15% to 20% complete response; see later).

IFN- α has also been studied in a combination treatment regimen with either chemotherapy or BCG (Bercovich et al, 1995; Stricker et al, 1996). There appeared to be additive effects with either epirubicin or MMC. Several trials investigated the combination of BCG and IFN and suggested the potential superiority of the combination or the possibility of decreasing the dose of BCG, which may reduce side effects. Initial pioneering work by O'Donnell and colleagues (1999) reported a 63% disease-free rate at 12 months and 53% at 24 months with use of combination therapy. In a larger trial of 1000 patients, 231 patients with CIS were evaluated. In those CIS patients in whom an induction course of BCG failed, the combination of low-dose BCG and IFN produced a 45% durable response at 2 years. However, in those patients who had CIS and were BCG naive, the BCG and IFN combination treatment resulted in 59% disease-free status at 24 months (Joudi et al, 2006a). Overall, patients in whom BCG alone failed within 12 months had a poor response to combination therapy. Of the non-responders to combination BCG and IFN, the majority of patients who experienced treatment failure with recurrence did so within 4 months of initial treatment (Grossman et al, 2008).

Investigational Immunotherapeutic Agents

A number of novel agents have shown potential, but none has reached clinical practice. Keyhole limpet hemocyanin (KLH) from the hemolymph of the mollusk *Megathura crenulata* is a nonspecific immune stimulant whose potential effectiveness in UC was identified serendipitously (Olsson et al, 1974; Jurincic et al, 1989). Recent work suggests continued promise for this agent, but no

BOX 93-3 Cleveland Clinic Approach to Management of Bacillus Calmette-Guérin (BCG) Toxicity**GRADE 1: MODERATE SYMPTOMS <48 HOURS**

Mild or moderate irritative voiding symptoms, mild hematuria, fever <38.5°C.

Assessment

Possible urine culture to rule out bacterial urinary tract infection.

Symptom Management

Anticholinergics, topical antispasmodics (phenazopyridine), analgesics, nonsteroidal anti-inflammatory drugs.

(Asymptomatic prostatic granulomas that occur after BCG therapy can occasionally mimic prostate cancer clinically and/or radiographically. There is no evidence to support treatment in this setting [Suzuki et al, 2013].)

GRADE 2: SEVERE SYMPTOMS AND/OR >48 HOURS

Severe irritative voiding symptoms, hematuria, or symptoms lasting >48 hr

All maneuvers for grade 1, plus the following:

Assessment

Urine culture, chest radiograph, liver function tests.

Management

Consult immediately with physician experienced in management of mycobacterial infections and complications.

Consider dose reduction to one half to one third of dose when instillations resume.

Treat culture results as appropriate.

Antimicrobial Agents

Administer isoniazid and rifampin, 300 mg/day and 600 mg/day, orally until symptom resolution.

Do not use monotherapy.

Observe for rifampin drug-drug interactions (e.g., warfarin).

GRADE 3: SERIOUS COMPLICATIONS (HEMODYNAMIC CHANGES, PERSISTENT HIGH-GRADE FEVER)**Allergic Reactions (Joint Pain, Rash)**

Perform all maneuvers described for grades 1 and 2, plus the following:

Isoniazid, 300 mg/day, and rifampin, 600 mg/day, for 3-6 mo depending on response.

Solid Organ Involvement (Epididymis, Liver, Lung, Kidney, Bone, Joint, Prostate)

Isoniazid, 300 mg/day; rifampin, 600 mg/day; ethambutol, 15 mg/kg/day single daily dose for 3-6 mo.

Cycloserine often causes severe psychiatric symptoms and is to be strongly discouraged.

BCG is almost uniformly resistant to pyrazinamide, so this drug has no role.

Consider prednisone, 40 mg/day, when response is inadequate or for septic shock (never given without effective antibacterial therapy).

From Walton Tomford, MD, Cleveland Clinic.

clear superiority to available agents (Lammers, 2012). Mycobacterial cell wall DNA extract contains a mixture of immunostimulatory DNA attached to antigenic cell wall. Phase II trial results indicate success rates less than those achieved with BCG, but with good tolerability; however, no agent is commercially available (Morales et al, 2001, 2009).

IL-2 is highly expressed after BCG stimulation and is a key component of the Th1 immune response. Preclinical data suggest a potential benefit and little toxicity (Horinaga et al, 2005). Multiple studies have documented the potential use of either intravesical IL-2 alone, with BCG, or with BCG and IFN (Shapiro et al, 2007). Preclinical data identifying the efficacy of liposome-mediated intravesical IL-2 with biologic response modifiers have elucidated long-term T-cell memory against muscle-invasive bladder cancer and non-muscle-invasive bladder cancer (NMIBC) (Horiguchi et al, 2000; Larchian et al, 2000).

KEY POINTS: IMMUNOTHERAPY

- Intravesical BCG has higher efficacy and side effects compared to intravesical chemotherapy.
- BCG should be used cautiously for patients with low-risk disease because of concern about side effects.
- Management of infectious complications of BCG is shown in Box 93-3.
- BCG is the only agent shown to delay or reduce high-grade tumor progression.
- The optimum dose and the treatment schedule for BCG are undetermined, but results are better with maintenance therapy, if tolerated.
- BCG is contraindicated in the setting of a disrupted urothelium because of the risk of intravasation and septic death.
- IFN- α has not been shown to have benefit compared with BCG for primary treatment but appears to work well in combination with low-dose BCG, especially for salvage.

INTRAVESICAL CHEMOTHERAPY

Induction therapy using chemotherapeutic agents instilled within 6 hours of TURBT has demonstrated a clear impact on recurrence rates, as described earlier. However, the role of chemotherapy in the adjuvant setting is less clear compared with the efficacy of BCG. A SWOG comparison of doxorubicin and BCG showed a 15% progression rate in BCG patients compared with a 37% progression rate in chemotherapy patients (Lamm et al, 1991). Nevertheless, the risk of BCG infectious complications is nonexistent with chemotherapy, leading many in the European community to favor this approach.

The agents are summarized in Table 93-3.

Mitomycin C

MMC is an alkylating agent that inhibits DNA synthesis. The drug is usually instilled weekly for 6 to 8 weeks at dose ranges from 20 to 60 mg. A meta-analysis of nine clinical trials compared its efficacy on progression with that of BCG. Within median follow-up of 26 months, 7.67% of the patients in the BCG group and 9.44% of the patients in the MMC group developed tumor progression (Bohle and Bock, 2004). Another review found a 38% reduction in tumor recurrence with MMC. This was not as effective as BCG but was considered in most studies to make MMC a viable option for reduction in recurrence (but not for progression) in light of its lesser side effects, particularly the low but real risk of BCG sepsis (Huncharek et al, 2001).

Optimization of MMC delivery can result in halving of the recurrence rate in some studies. This can be achieved by eliminating residual urine volume, fasting overnight, using sodium bicarbonate to reduce drug degradation, and increasing concentration to 40 mg in 20 mL (Au et al, 2001). The use of local microwave therapy in

TABLE 93-3 Comparisons among Intravesical Agents

AGENT	PERIOPERATIVE USE	RISK GROUP	CYSTITIS (%)	OTHER TOXICITY	DROPOUT (%)	CONCENTRATION AND DOSE
Doxorubicin (Adriamycin)	Yes	Low to intermediate	20-40	Fever, allergy, contracted bladder, 5%	2-16	50 mg/50 mL
Epirubicin	Yes	Low to intermediate	10-30	Contracted bladder rare	3-6	50 mg/50 mL
Thiotepa	Yes	Low to intermediate	10-30	Myelosuppression 8%-19%	2-11	30 mg/30 mL
Mitomycin	Yes	Low to intermediate	30-40	Rash 8%-19%, contracted bladder 5%	2-14	40 mg/20-40 mL
BCG	No	Intermediate to high	60-80	Serious infection, 5%	5-10	1 vial/50 mL
Interferon	No	Salvage	<5	Flulike symptoms 20%	Rare	50-100 MU/50 mL

BCG, bacille Calmette-Guérin.

Modified from O'Donnell MA. Practical applications of intravesical chemotherapy and immunotherapy in high-risk patients with superficial bladder cancer. *Urol Clin North Am* 2005;32:121-31.

conjunction with MMC, 20 mg/50 mL, reduced recurrence rates from 57.5% to 17.1% in a multicenter trial. A study using microwave therapy with higher doses of 40 to 80 mg for 6 to 8 weeks in high-grade bladder cancer found a recurrence-free rate of 75% at 2 years (Gofrit et al, 2004; van der Heijden et al, 2004).

Electromotive intravesical MMC appears to improve drug delivery into bladder tissue (Di Stasi and Riedl, 2009). This treatment reported reduction in recurrence rates with MMC from 58% to 31%, whereas patients in the BCG control arm had a 64% recurrence rate (Di Stasi et al, 2003). Peak plasma MMC was significantly higher in the electromotive group, supporting its reputed mechanism of action. Electromotive intravesical MMC remains unavailable in the United States.

Doxorubicin and Its Derivatives

Doxorubicin (Adriamycin) is anthracycline antibiotic that acts by binding DNA base pairs, inhibiting topoisomerase II, and inhibiting protein synthesis. In a review, doxorubicin demonstrated a 13% to 17% improvement over TUR in preventing recurrence but no advantage in preventing tumor progression (15.2% vs. 12.6%) (Kurth et al, 1997). The principal side effect of intravesical doxorubicin is chemical cystitis, which can occur in up to half of patients. Reduced bladder capacity has been reported in several series (Thrasher and Crawford, 1992).

The doxorubicin derivative epirubicin decreases recurrence compared with TUR alone by 12% to 15% (Oosterlinck et al, 1993). This was demonstrated with a single, immediate, perioperative dose, as well as in full 8-week courses of intravesical therapy. Epirubicin is available for UC in Europe and is FDA approved but is unavailable for treatment of UC in the United States.

Valrubicin is a semisynthetic analog of doxorubicin that was approved by the FDA for treatment of BCG-refractory CIS in patients who cannot tolerate cystectomy; the drug became available in 2009 in the United States (Sweatman et al, 1991; Greenberg et al, 1997; Grossman et al, 2008). In a cohort of 90 patients with BCG-refractory CIS, only 21% demonstrated a complete response (Steinberg et al, 2000), so its use is not widespread.

Thiotepa

Thiotepa (triethylenethiophosphoramidate) is the only chemotherapeutic agent approved by the FDA specifically for the intravesical treatment of papillary bladder cancer. It is an alkylating agent and is not cell cycle specific. In controlled clinical trials (N = 950 patients), it has been shown to significantly decrease tumor recurrence

in 6 of 11 studies by up to 41% (mean decrease, 16%). Systemic side effects can be seen owing to its low molecular weight, resulting in up to half of administered doses being absorbed, risking hematopoietic toxicity (Thrasher and Crawford, 1992). Nevertheless, most centers have substituted its use with BCG or the aforementioned chemotherapeutic agents.

Novel Agents

Gemcitabine and the taxanes paclitaxel and docetaxel have demonstrated activity against metastatic bladder cancer (Calabro and Sternberg, 2002). Intravesical gemcitabine can be safely administered either weekly or twice weekly for six to eight treatments. Minimal systemic absorption occurs through the bladder. Several small phase I and phase II studies have demonstrated reduction of recurrence of 39% to 70% including modest efficacy in heavily pretreated BCG-refractory patients (Maymi et al, 2004; O'Donnell, 2005). Taxanes have been formulated into an active intravesical treatment, but current published data are limited to preclinical studies (Lu et al, 2004).

Combination Therapy

Combining mechanisms of different agents is a logical and often successful approach to improve response rates for systemic therapy. However, studies have not identified clear benefit to doing so in intravesical therapy. For instance, in the study by Fukui and coworkers (1992), MMC (20 mg) was administered on day 1 and doxorubicin (40 mg) on day 2 once a week for 5 weeks in 101 patients. Fifty-one patients demonstrated a complete response and were further randomized to maintenance or no maintenance. Local side effects were significant in 50% of patients. Patients with CIS had fewer recurrences with maintenance therapy. Other studies demonstrated similar outcomes, with a general theme of increased local side effects with modest outcome improvement (Isaka et al, 1992; Sekine et al, 1994).

A combination of chemotherapy and BCG was evaluated in prospective trials by several investigators. The EORTC reported a 46% complete response rate when a solitary marker tumor was intentionally not resected and patients were subsequently given sequential MMC and BCG (van der Meijden et al, 1996). In a study of 188 patients with Ta and T1 lesions, no difference was seen with regard to recurrence, progression, or side effects in those patients treated with BCG and MMC compared with those treated with MMC alone. There was actually a significantly longer disease-free interval in the BCG monotherapy arm (55%) compared with the

same combination arm (45%) in another study of 314 patients (Malmstrom et al, 1999; Solsona et al, 2002). Thus no clear advantage is obtained with sequential therapy, combination chemotherapy, or chemotherapy and BCG regimens using any of the combinations explored to date (Rintala et al, 1995, 1996; Witjes et al, 1998; Nieder et al, 2005).

KEY POINTS: INTRAVESICAL CHEMOTHERAPY

- Intravesical chemotherapy has a clear impact on tumor recurrence when immediately instilled after TURBT and in the adjuvant setting. There is no clear evidence of an impact on progression.
- Combinations of various chemotherapeutic agents and chemotherapy combined with BCG have not demonstrated major benefit combined with single-agent treatment, with the exception of IFN.
- In general, side effects of chemotherapy tend to be less common and less severe than those for BCG, but BCG is more efficacious.

REFRACTORY HIGH-GRADE DISEASE

Recurrent or persistent disease after an initial 6-week course of BCG has been traditionally referred to as *BCG failure*, although this term has been poorly defined in the past. Current consensus is that persistent disease after BCG therapy can be categorized as BCG refractory (nonimproving or worsening disease despite BCG), BCG resistant (recurrence or persistence of lesser degree, stage, or grade after an initial course, which then resolves with further BCG), or BCG relapsing (recurrence after initial resolution with BCG). BCG-refractory patients in particular are an especially high-risk group and should be strongly considered for immediate cystectomy if young and in generally good health (Herr and Dalbagni, 2003). Intravesical treatment should be reserved for patients who refuse or are too ill to undergo cystectomy or on defined investigational protocols.

The necessity of biopsy to determine BCG response is unclear, although it should be strongly considered in high-risk patients to determine disease status at this key point in time. Urine cytology can be useful in this setting. Dalbagni and colleagues (1999) reported minimal usefulness of routine biopsy after BCG if cystoscopy and urinary cytology were both negative. Whereas 5 of 11 patients with erythematous bladder mucosa and positive cytology had positive bladder biopsies, none of 37 with erythematous lesions and negative cytology were positive, and only 1 in 13 patients with a normal mucosa had a positive biopsy (Dalbagni et al, 1999). Other studies have suggested that the value of routine post-BCG biopsy is limited (Dalbagni et al, 1999). UroVysion FISH (Abbott Molecular, Chicago, IL) conversion from positive to negative has been shown to correlate with BCG response in single-center studies (Kipp et al, 2005; Whitson et al, 2009).

Declaring failure may take up to 6 months because the response rate for patients with high-grade bladder cancer treated with BCG rose from 57% to 80% 3 to 6 months after therapy. Clearly, the tumoricidal activity continued for some period after cessation of therapy. This has obvious implications not only for declaring BCG failure and the need for subsequent therapy but also for interpretation of success rates of salvage protocols if administered soon after therapy (Herr and Dalbagni, 2003).

Management of Refractory High-Grade Disease

Although most urologists will administer an initial 6-week course of intravesical therapy for high-risk patients (most likely involving BCG in North America and chemotherapy in Europe), management of patients with persistent disease after the first course is more complex. Such patients are at increased risk of progression,

which is particularly likely in the event of early recurrence, progression while on therapy, or multiple recurrences.

If the initial treatment was chemotherapy, a course of BCG should be considered. BCG has demonstrated superiority to repeat courses of chemotherapy in this setting because the latter will lead to only an approximately 20% disease-free survival (Malmstrom et al, 1999; Steinberg et al, 2000). For patients who have failed BCG, a second course still gives a 30% to 50% response (Pansadoro and De Paula, 1987; Brake et al, 2000). Patients who cannot tolerate BCG for any reason may be considered for salvage chemotherapy, but the risk of failure and progression is high.

Further courses of BCG or chemotherapy beyond two are not recommended because they will fail 80% of the time, although recent studies suggest some potential for newer agents (Skinner et al, 2013). Rapid disease progression is common in such patients, so salvage chemotherapy, investigational protocols, and IFN alone or in combination with reduced doses of BCG may be appropriate only for patients who are unwilling or unable to undergo surgery even after being informed of their risks (Catalona et al, 1987).

The combination of IFN- α with BCG is expensive and has not been shown superior to BCG alone in primary therapy, so it has been used mostly for BCG failures. Small single-institution studies using low-dose BCG (typically one-third dose) plus 50 to 100 million units of IFN- α have demonstrated 1- to 2-year success rates of 50% to 60%, with better results with a second reinduction option and three sets of 3-week miniseries maintenance treatments 3, 9, and 15 months later (O'Donnell et al, 2001; Lam et al, 2003; Punnen et al, 2003). A large national multicenter phase II trial of combination BCG plus IFN- α in BCG-naïve and BCG-failure patients revealed similar findings (O'Donnell et al, 2004). Estimates for freedom from disease at 2 years were 57% for BCG-naïve patients and 42% for BCG-failure patients. Progression was seen in only 8% of patients in each group, suggesting that this combination has a potential role regardless of prior BCG response.

Role of Alternative Options for Refractory Disease

Photodynamic therapy (PDT) is performed by administering a photosensitizing agent such as porfimer sodium (Photofrin) systemically or HAL intravesically. Two to 3 days after the substance has cleared from the normal tissue (for Photofrin), the patient is given an intravesical treatment with red laser light (630 nm) for 12 to 20 minutes. Intravesical intralipid allows for more uniform distribution of laser light (Manyak et al, 1990). After excitation by light, the photosensitizer reacts with molecular oxygen to form free radicals and reactive singlet oxygen, which are cytotoxic.

The response rate in CIS patients from combined series is 66%, with a duration of 37 to 84 months (Jocham et al, 1989; Nseyo et al, 1997, 1998; Walther, 2000). For patients with papillary disease, an overall response rate of 51% has been achieved with a median time to recurrence of 24 to 48 months (Naito et al, 1991; Nseyo et al, 1997, 1998; Walther, 2000). PDT has been limited by significant side effects such as bladder contracture or irritability (50%) and dermal sensitivity (19%) (Naito et al, 1991; Uchibayashi et al, 1995; Nseyo et al, 1997, 1998).

Research efforts have been directed at development of improved photosensitizers and modifications in laser dosimetry (Kriegmair et al, 1996a; Nseyo et al, 1997, 1998). HAL, a more lipophilic ester of 5-ALA, generates a sensitizer called *protoporphyrin IX* that appears more tumor specific, although clinical data are limited (Datta et al, 1998). Preclinical studies using hypericin have shown promise (Kamuhabwa et al, 2004). Radachlorin is composed of three chlorins and appears promising, at least in the setting of BCG-refractory high-grade disease (Lee et al, 2013).

Radiation therapy in the treatment of NMIBC is typically restricted to individuals who refuse cystectomy after the failure of intravesical therapy or who are unsuitable for major surgery (Kim et al, 2000). A complete response to radiation therapy and TUR is attainable in 50% to 75% of patients, but the additional benefit of radiation to TUR remains unclear (De Neve et al, 1992; Rozan et al,

1992; Jansson et al, 1998). Five-year response rates are 44% to 60%. There is no significant effect on CIS. Owing to reports that up to 50% of patients will develop progression and a high likelihood of death (Rödel, 2001), there is a limited role for radiation therapy other than for palliative purposes in this population. Combinations of radiation and chemotherapy have shown promise but have not reached widespread use (Gray et al, 2013).

KEY POINTS: MANAGEMENT OF REFRACTORY DISEASE

- Patients who experience failure of an initial course of intravesical therapy after TURBT are at high risk of recurrence or progression.
- Failure of initial chemotherapy or BCG is most appropriately treated with a subsequent course of BCG because its efficacy in this setting is significantly greater than that of chemotherapy.

ROLE OF “EARLY” CYSTECTOMY

Despite local therapy, many cases of high-grade NMIBC will progress to invasion and risk of cancer death. Although the initial response rate to BCG therapy in CIS patients can be above 80%, patients in whom treatment fails will have a 50% chance of disease progression and potential for disease-specific mortality (Catalona et al, 1987; Nadler et al, 1994). Early (3-month) failure for T1 tumors after BCG is associated with an 82% progression rate, compared with a 25% progression rate in patients who do not experience treatment failure at 3 months (Herr et al, 1997; Herr, 2000a). Up to 20% of patients with CIS will die of UC within 10 years (Herr et al, 1989); each occurrence of T1 tumors is associated with a 5% to 10% chance of metastasis (Herr and Sogani, 2001), and residual tumor found on repeat resection in these patients is associated with an 82% chance of development of muscle invasion (Herr et al, 1997). These data offer compelling evidence of the potential to underestimate disease status in high-risk patients.

Cookson and coworkers (1997) reported that 27% of high-risk patients treated initially with aggressive intravesical therapy did well and died of other causes, and the same low number survived with an intact, functioning bladder 15 years after diagnosis. However, approximately half of patients experienced progression, and one third died of their disease. In contrast, patients who undergo immediate cystectomy for clinical T1 tumors benefit from more accurate pathologic staging in addition to a 10-year disease-free survival of 92%, compared with 64% of those with clinical T1 tumors who were found to actually have muscle invasion at the time of cystectomy (Bianco et al, 2004).

Despite the benign connotation of the term *superficial* formerly applied, up to 50% of patients with presumed non-muscle-invasive high-grade disease who undergo cystectomy will actually be found to have muscle-invasive disease. Such procedures have traditionally been termed *early cystectomy* on the basis of the fact that they are performed before the traditional surgical indication of documented muscle invasion. Considering that up to 15% will already have micrometastases (Chang and Cookson, 2005) and that a delay in cystectomy of even 12 weeks is associated with poorer survival, some of these procedures do not seem to be early enough (Sanchez-Ortiz et al, 2003; Chamie, 2013).

The risk of progression must be weighed against the risk, morbidity, and impact on quality of life for cystectomy. Thus a reasonable goal might be, as termed by Chang and Cookson (2005), “timely” cystectomy for patients at risk.

Ten-year survival after cystectomy for non-muscle-invasive cancer can range from 67% to 92% (Amling et al, 1994; Freeman et al, 1995). However, despite the bias that substantial progression can be averted with the benefit of early detection and close surveillance in patients whose tumors are identified before

muscle invasion, it appears that such patients who progress to having muscle invasion may have a poorer prognosis than do those who have muscle-invasive disease on initial presentation (Schrier, 2004; Lee et al, 2007). Thus overconfidence in disease control status with high-risk patients on surveillance creates a false sense of security.

The AUA guidelines panel listed cystectomy as the first option for patients with refractory high-grade disease after an initial course of intravesical therapy (see later). Nevertheless, fewer than one in five American urologists surveyed stated that they would recommend cystectomy for their patients with CIS refractory to two courses of intravesical BCG, a group with an 80% risk of failure or progression (Joudi et al, 2006a). Cystectomy in that setting, or for persistent high-grade papillary disease after two courses of intravesical therapy, is the standard of care and should not be considered “early.”

Some series suggest that tumor markers such as p53 and RB may be useful for stratifying high-risk patients for such decisions in the future. High-risk p53 lesions have a 75% progression rate, compared with 25% in p53-negative lesions. Survival is 60% at 10 years in patients with p53-positive lesions, whereas it is 88% in patients with p53-negative lesions (Sarkis et al, 1993). Grossman and colleagues (1998) found that for T1 lesions evaluated for p53 and RB, progression at 5 years was 30% if either marker was positive and 47% if both markers were positive. No progression was noted in lesions that were wild type for both markers (Grossman et al, 1998). Although p53 positivity did not predict response for BCG-treated patients in another study, post-BCG p53-positive expression was a marker of tumor progression (p53 positive, 82% progression and 41% mortality; p53 negative, 13% progression and 7% mortality) (Lacome et al, 1996). Other studies have refuted these findings, so the role of p53 for the prediction of tumor behavior and response to therapy remains under debate (Peyromaure et al, 2002).

The role of surgical approaches involving potential oncologic concessions such as seminal and nerve-sparing cystectomy in such patients theoretically at lower risk of recurrence compared with patients with muscle invasion remains unknown (Hautmann and Stein, 2005). The availability of neobladder for less disfiguring urinary diversion has been reported to decrease the delay in treatment of such patients, potentially leading to significantly improved disease-free survival (Hautmann, 1998). The impact on disease outcomes is unproven.

Critical evaluation of partial cystectomy for NMIBC is limited, although the practice is common (up to 20% of patients treated with extirpative therapy in the United States) even in patients with muscle invasion (Hollenbeck et al, 2005). Holzbeierlein and colleagues (2004) reported that 6.9% of the patients at Memorial Sloan-Kettering Cancer Center for surgical management of bladder cancer underwent partial cystectomy (29% of whom did so for clinical non-muscle-invasive disease). Five-year survival was 69%, and two thirds of patients were alive with an intact, functioning bladder. CIS was the most significant predictor of progression.

Partial cystectomy provides more accurate pathologic staging than does TURBT and allows lymphadenectomy. Appropriate candidates with non-muscle-invasive tumors would logically be the same as those for invasive cancer—those with solitary tumors at the dome or well away from the trigone and no CIS.

Cystectomy should also be considered in patients whose cancer cannot be reasonably controlled through resection: bulky tumors, inaccessible because of a large bladder or urethral stricture disease, or otherwise not amenable to safe removal endoscopically.

In summary, radical cystectomy offers the most accurate pathologic staging option and should be strongly considered for patients with NMIBCs that are high grade and invading deeply into lamina propria, exhibit lymphovascular invasion, are associated with diffuse CIS, are in diverticula, substantially involve the distal ureters or prostatic urethra, are refractory to initial therapy, or are too large or anatomically inaccessible to be removed in their entirety endoscopically. It can also be used in patients who understand the risks and benefits of bladder preservation versus cystectomy and request definitive therapy (Stein, 2003). Partial

cystectomy has limited data but might be a promising bladder preservation option situated between the extremes of TURBT combined with intravesical therapy and radical cystectomy.

KEY POINTS: EARLY CYSTECTOMY

- Patients at high risk for progression should be considered for cystectomy.
- Failure to respond to an initial course of intravesical therapy is occasion to reconsider cystectomy.
- Failure to respond to a second course is an indication for immediate cystectomy unless contraindicated or the patient chooses to pursue clinical trials or newer proven intravesical options if evidence builds for their use.

SURVEILLANCE AND PREVENTION

Although bladder cancer is less common than prostate cancer, expenditures are almost twice as high for bladder cancer because of its chronic nature and the need for long-term surveillance. According to the Agency for Healthcare Research and Quality, annual expenditures were \$2.2 billion in 2003 for bladder cancer versus \$1.4 billion for prostate cancer (Donat, 2003). A significant portion of this cost is associated with surveillance (Hedelin et al, 2002).

Surveillance strategies for UC recurrence have historically relied on the diagnostic combination of cystoscopy and urinary cytology. In clinical practice, only 40% of patients actually comply with a standard surveillance protocol (Schrage et al, 2003). Most protocols include this combination every 3 months for 18 to 24 months after the initial diagnosis, then every 6 months for the following 2 years, and then annually, resetting the clock with each newly identified tumor (Fitzpatrick, 1993). Although the accuracy of both tests relies on subjective and operator-dependent interpretation of visible findings, their traditional presumed status as the gold standard has been widely accepted (Brown, 2000).

Cystoscopic Surveillance

Office-based cystoscopy offers rapid, relatively painless visual access to the urothelium. Papillary tumors arising from the smooth bladder surface are readily identified. CIS is classically described as a velvety red mucosal patch, although the reliability of such findings has been called into question.

The role of cystoscopy as a gold standard in cancer detection has come under scrutiny with the emergence of tumor markers and the development of newer endoscopic technology including fluorescence cystoscopy as described previously (Kriegmair et al, 1996a, 1996b; Filbeck et al, 1999; Kriegmair et al, 1999). Nevertheless, for office-based diagnosis it allows identification of the site and characteristics of most tumors. There is a high positive predictive value with cystoscopy because most lesions believed to be malignant are proven so pathologically. The endoscopic appearance cannot reliably predict tumor stage or grade, although sessile morphology and/or the presence of necrosis suggests high-grade disease likely to be invasive.

Cystoscopy is usually performed in the outpatient setting. Rigid rod-lens systems offer accurate visualization of the bladder. Flexible fiberoptic cystoscopes are almost as sensitive and are markedly more comfortable for men, although there is no clear advantage to their use in women because of the short, straight female urethra. Newer digital chip cystoscopes offer similar tolerability but markedly better visualization owing to clarity and magnification on video monitors. Complete visualization of the bladder mucosa is possible in a matter of seconds in most patients. Their high-resolution imaging obviates the only potential advantage of rigid cystoscopy (slightly better optics than fiberoptic flexible scopes). Thus, flexible cystoscopy has essentially replaced rigid cystoscopy for surveillance in men in North America and may do so in women.

Using the same technology for flexible cystoscopy as described earlier for HAL fluorescence rigid cystoscopy, phase II studies have had mixed results but suggest that office-based fluorescence cystoscopy can improve the detection of CIS and papillary tumors (Loidl et al, 2005; Witjes et al, 2005).

The vast majority of both men and women tolerate office-based cystoscopy with minimal discomfort. Intraurethral injection of local anesthetics is almost universal among urologists despite a paucity of data to support the practice. Most studies and a meta-analysis (Patel et al, 2008b) have failed to identify benefit (Palit et al, 2003; Rodriguez-Rubio et al, 2004), and two recent studies actually found that pain experience was higher with the use of local anesthetics than in patients cystoscoped using aqueous lubricant alone (Ho et al, 2003; Chen et al, 2005). Considering the fact that anesthetic agents can partially cloud visualization, this ubiquitous practice should be reconsidered. Use of a video monitor allows the patient to see and understand the findings, theoretically distracting them from any discomfort. Men who are able to do so tolerate the procedure with approximately 50% less pain (visual analog scale 2.21 vs. 1.31, $P < .01$) than those who cannot see their findings on the monitor (Patel et al, 2007). This has not been found to be of significant benefit in women, probably because of the straighter urethra (Patel et al, 2008a).

The bladder should be evacuated before cystoscopy. This removes concentrated amorphous detritus and radiographic contrast if studies were performed earlier in the day. Aspiration with use of a 60-mL syringe attached to the irrigant port is occasionally necessary during the procedure. This can further lessen clouding. A systematic approach is mandatory to ensure that all urothelium is visualized.

Attempts have been made to modify the previously described surveillance schedule with use of decision analysis tools (Kent et al, 1989; Abel, 1993). Several authors recommend termination of surveillance at 5 or more years for low-risk patients (Haukaas et al, 1999). However, the actual cost of surveillance cystoscopy was responsible for only 13% of the expenditures for bladder cancer care in one study, so the financial opportunity may be limited for such efforts (Schoenberg et al, 2000; Hedelin et al, 2002). In addition, the risk of recurrence and potential for progression exists beyond this period. Reports of late recurrences of high-grade cancer years after the original tumor temper some authors' enthusiasm for terminating surveillance at any point (Thompson et al, 1993; Morris et al, 1995; Leblanc et al, 1999; Zieger et al, 2000). Thus there is no consensus on such programs.

Other investigators have examined the predictive impact of early or multiple recurrences and how this might affect surveillance (Parmar et al, 1989; Holmäng et al, 1995; Reading et al, 1995). Tumor recurrence on initial 3-month cystoscopy and number of tumors on initial resection (single or multiple) provides the most predictive information with regard to recurrence in several studies. Absence of recurrence on the 3-month surveillance cystoscopy in patients with Ta low-grade tumors is associated with recurrence rates so low that annual cystoscopy appears safe even at that point (beginning 12 months after the initial resection (Fitzpatrick et al, 1986; Olsen and Genster, 1995; Frydenberg et al, 2005). Finally, patients with a negative cystoscopy and a negative UroVysion assay (see later) are at low risk of recurrence in the following 6 to 12 months, creating opportunity to individualize the surveillance schedule (Sarosdy et al, 2002).

Urine Cytology

Cytology involves microscopic evaluation of stained cellular smears from the urine. Unlike tumor markers, urinary cytology is not a laboratory test—it is a pathologist's interpretation of the morphologic features of shed urothelial cells. Poor cellular cohesion in high-grade tumors, especially CIS, enhances the yield.

Its high specificity is the most important feature of cytology because a positive reading regardless of cystoscopic or radiographic findings suggests the existence of malignancy in the vast majority of patients. Even in the setting of UC, of patients with a

negative workup (cystoscopy and upper tract imaging) with a persistently positive cytology, 40% were found to have genitourinary cancer within 24 months (Nabi et al, 2004).

Bladder irrigation or barbotage increases the cellularity available for evaluation compared with voided urine. Nevertheless, Murphy and colleagues (1981) showed that urine collected cystoscopically before a bladder wash was obtained provided additional diagnostic information. Bladder washings had a higher yield, but 13.1% of cancers would have been missed in bladder washings alone. Moreover, mechanical trauma has the potential to create cellular alterations that might interfere with interpretation. Radiographic contrast media have also been implicated in creating cellular shrinkage, nuclear pyknosis, fragmentation, and cytoplasmic vacuolization that might lead to a false-positive reading, especially when injected for retrograde ureteropyelography (McClennan et al, 1978). This may not be a concern when low osmolar, ionic and nonionic, contrast media are used (Andriole et al, 1989).

Although cytology has traditionally been believed to have high sensitivity for high-grade cancer, recent studies do not support this. Mayo Clinic researchers observed that only 58% of bladder tumors were identified using cytology. Its sensitivity was not limited to low-grade tumors because only 71% of high-grade cancers were identified. Because this was lower than expected, they subsequently reviewed the literature and found that cumulative data from series published after 1990 reported that cytology actually identified (using the older grading system) 11% of grade 1, 31% of grade 2, and only 60% of grade 3 tumors (Halling et al, 2000). In contrast, they observed that these recent findings were well below those reported before 1990, when the sensitivity of cytology was 94% for grade 3 tumors, but could find no explanation for this deterioration. These findings are supported by numerous other studies and emphasized by a recent multicenter study involving several institutions noted for bladder cancer expertise that found cytology had an overall sensitivity of 15.8%, and 37.5% for patients with high-grade tumors (Grossman et al, 2005).

Thus cytology has high specificity but low sensitivity for both high-grade and low-grade tumors including CIS in recently published reports.

Tumor Markers

Many attempts have been made to develop a UC biomarker test to complement or replace urinary cytology. Most of these have had adequate sensitivity but poor specificity, resulting in substantial false-positive readings, creating the need for further diagnostic testing. Current urinary markers have been developed to detect tumor-associated antigens, blood group antigens, growth factors, cell cycle and apoptosis, and extracellular matrix proteins. The most significant issue limiting widespread adoption of tumor markers is the lack of prospective data to support their impact on prognosis or disease management (Lokeshwar et al, 2005).

The qualitative point-of-care test **BTA stat** (Polymedco, Cortlandt Manor, NY) and the quantitative **BTA TRAK** (Polymedco) assay detect human complement factor H-related protein. The overall sensitivity of these tests ranges from 50% to 80%, whereas the specificity is between 50% and 75%. These tests are more sensitive than cytology, but their results can be falsely positive in patients with inflammation, infection, or hematuria (Liou, 2006).

ImmunoCyt (DiagnoCure, Saint Foy, Canada) is a hybrid of cytology and an immunofluorescence assay. Three fluorescent-labeled monoclonal antibodies are targeted at a UC variant of carcinoembryonic antigen and two bladder mucins. Sensitivity and specificity are reported to be 86% and 79%, respectively. The assay has not been shown to be affected by benign conditions, but interpretation is complex and operator dependent (Toma, 2004; Têtu, 2005).

The **NMP22 BladderChek Test** (MatriTech, Newton, MA) is based on the detection of nuclear matrix protein 22, part of the mitotic apparatus released from urothelial nuclei on cellular apoptosis. The protein is elevated in UC, but it is also released from dead and dying urothelial cells. Benign conditions of the urinary tract such as stones, infection, inflammation, hematuria, and cystoscopy

can cause a false-positive reading. Both a laboratory-based, quantitative immunoassay and a qualitative point-of-care test are available. The sensitivities and specificities range from 68.5% to 88.5% for sensitivity and from 65.2% to 91.3% for specificity (Liou, 2006). A multi-institutional trial involving 1331 patients showed that, overall, the NMP22 was more sensitive than cytology but less specific. Sensitivities were 50% and 90% for noninvasive and invasive cancer, respectively, with an overall sensitivity of 55.7%. Overall specificity was higher for cytology at 99.2% compared with NMP22 at 85.7%. The sensitivity of cystoscopy in this study was 88.6%, but when combined with NMP22, this increased to 93.7% (Grossman et al, 2005).

UroVysion (Abbott Molecular, Chicago, IL) is a cytology-based test that uses FISH of DNA probes or labels specifically chosen to identify certain chromosomal foci. Probes to identify aneuploidy of chromosomes 3, 7, and 17 are combined with a probe to the 9p21 locus. Probes can be developed to identify essentially any locus, but this combination has the best sensitivity and specificity (Halling et al, 2000). Cumulative data from comparative studies show sensitivity for cytology compared with FISH of 19% versus 58% for grade 1, 50% versus 77% for grade 2, and 71% versus 96% for grade 3. Similar findings occurred by stage, wherein cytology compared with FISH sensitivity was 35% versus 64% for Ta, 66% versus 83% for T1, and 76% versus 94% for muscle-invasive carcinoma (Jones et al, 2006).

Notably, cytology detected only 67% of patients with CIS versus 100% detection by FISH in comparative studies. **UroVysion has the highest specificity of the available tumor markers.** It will, however, detect chromosomal changes before the development of phenotypic expression of malignancy, so it leads to an “anticipatory positive” reading in some patients. Such readings are often not false positives and will lead to identification of clinical tumors within 3 to 15 months in the majority of cases (Sarosdy et al, 2002). Moreover, patients testing negative are unlikely to experience tumor recurrence in less than 1 year (Yoder et al, 2007). This may allow identification of patients at risk of recurrence versus those unlikely to develop recurrence, to individualize surveillance protocols.

UroVysion has also been shown to clarify equivocal findings in patients with atypical or negative cytology (Skacel et al, 2003). It is not affected by hematuria, inflammation, or other factors that can cause false-positive readings with some tumor markers, so it appears to be useful as a marker of BCG response (Kipp et al, 2005; Whitson et al, 2009). “Nondiagnostic” UroVysion reports identifying limited cellularity or positive cells at numbers below defined standards can be regarded as negative and are not associated with increased risk of bladder cancer recurrence in the future compared with expectations with “normal” readings (Nguyen et al, 2009).

A retrospective study suggests that a multiplex of eight biomarkers in combination may improve performance compared with currently available markers if validated in further studies (Rosser et al, 2013).

The usefulness of tumor markers and the choice of which one to use is not clear at this time. For example, if indication for biopsy in the operating room is the end point, then high specificity is desired to limit the number of negative biopsies. On the other hand, if increasing the interval of cystoscopic surveillance is the end point, then high sensitivity, particularly for high-grade tumors, is desired. Defining that a patient has a low likelihood of recurrence within the following year can allow individualization of surveillance protocols (Fig. 93-8) (Grossman et al, 2006).

Extravesical Surveillance

The proportion of patients developing upper tract UC after treatment of non-muscle-invasive disease has been reported as 0.002% to 2.4% over intervals of 5 to 13 years (Shinka et al, 1988; Oldbring et al, 1989; Holmäng et al, 1995; Sadek et al, 1999), although the risk increases substantially over time to as high as 18% in very high-risk populations (Herr et al, 1997). Synchronous tumors were detected in no patients (0%) with grade 1 (using the prior grading system) tumors, 1.1% with grade 2, and 1.3% with grade 3, as well as 0% for low-grade Ta and 7% for T1 (Herranz-Amo et al,

TABLE 93-4 Suggested Surveillance Strategies

RISK	TUMOR STATUS	CYSTOSCOPY SCHEDULE	UPPER TRACT IMAGING
Low	Solitary Ta low grade	3 mo after initial resection Annually beginning 9 mo after initial surveillance if no recurrence Consider cessation at 5 or more yr Consider cytology or tumor markers	Not necessary unless hematuria present
Intermediate	Multiple Ta low grade Large tumor Recurrence at 3 mo	Every 3 mo for 1-2 yr Semiannually or annually after 2 yr Consider cytology or tumor markers Restart clock with each recurrence	Consider imaging, especially for recurrence Imaging for hematuria
High	Any high grade (including CIS)	Every 3 mo for 2 yr Semiannually for 2 yr Annually for lifetime Cytology at same schedule Consider tumor markers Restart clock with each recurrence	Imaging annually for 2 yr, then consider lengthening interval

CIS, carcinoma in situ.

Figure 93-8. An abnormal enlarged cell (lower right) demonstrates three copies of chromosome 3 (red), chromosome 7 (green), and chromosome 17 (aqua) on use of fluorescence in situ hybridization. Homozygous deletion of band 9p21 locus (yellow) is also present. (Courtesy Raymond Tubbs, MD, Department of Laboratory Pathology, Cleveland Clinic Foundation.)

1999). The Surveillance, Epidemiology, and End Results (SEER) database showed that only 0.8% of bladder cancer patients develop subsequent upper tract tumors, so surveillance is of limited value unless the patient has hematuria or a high-grade tumor, especially if it is near the ureteral orifice (Wright et al, 2009). In a review of 591 patients with median follow-up of 86 months, upper tract recurrence was 0.9% in low-risk patients (solitary, low-grade, low-stage Ta/T1), 2.2% in patients at intermediate risk (recurrent or multifocal disease), and 9.8% in high-risk patients including intravesical chemotherapy failures (Hurle et al, 1998). Most reviews have concluded that patients who have high-grade

or multiple tumors should undergo upper tract imaging on the basis of the risk of upper tract disease, but those with low-grade tumors probably do not benefit from imaging unless performed for hematuria.

The proper study to evaluate the upper tract is debatable. Excretory urography is the traditional choice but gives limited information about renal parenchyma and can miss small tumors. Retrograde ureteropyelography requires instrumentation, but this is often not a problem because these patients require removal of the primary bladder tumor, so the procedures can be combined. Multiphasic computed tomography (CT) urography has become the preferred technology for the evaluation of hematuria, but its role in the evaluation of patients with NMIBC has not been extensively reported (Herts, 2003; Davis et al, 2012).

Although infrequent, the appearance of upper tract disease is associated with mortality rates of 40% to 70%. Patients with high-risk disease treated with BCG experience upper tract recurrence risk of 13% to 18% (Miller et al, 1993; Herr et al, 1997). The risk for recurrence in this population appears greatest over the first 5 years after treatment (median time to detection, 56 months) yet persists at least 15 years.

Selective cytology of the upper tract may increase the yield of upper tract lesions detected, but, in the presence of a bladder tumor, selective upper tract cytology may be falsely positive and is not recommended for most patients (Zincke et al, 1983; Sadek et al, 1999).

Secondary tumor involvement of the prostatic urethra and ducts by UC may be detected in 10% to 15% of patients with high-risk non-muscle-invasive disease within 5 years and in 20% to 40% within 10 years (Donat, 2003). Patients who have refractory disease are at risk for extravesical recurrence in the prostatic fossa in approximately one third of cases, 44% of which are fatal (Herr et al, 1988). Involvement of the prostatic ducts by low-grade UC should usually be managed by complete TURP for disease eradication and to facilitate contact of intravesical therapy to the prostatic urethra. Involvement of the ducts by high-grade disease is best managed by radical cystoprostatectomy, and consideration of urethrectomy should be made, especially if tumor is present near or at the surgical margin (Liedberg et al, 2007).

In summary, surveillance strategies should be individualized on the basis of the risk of recurrence in the bladder and extravesical sites (Table 93-4).

SECONDARY PREVENTION STRATEGIES

Both lifestyle changes and chemoprevention could potentially reduce the risk of recurrence and have been considered in the management of patients with non-muscle-invasive disease.

BOX 93-4 American Urological Association 2007 Guidelines for Non-Muscle-Invasive Bladder Cancer**INDEX PATIENT NO. 1: ABNORMAL UROTHELIAL GROWTH BUT NOT PROVEN CANCER**

Standard: Obtain biopsy to confirm grade for all index patients.

If possible, eradicate all visible tumors.

If cancer, periodic cystoscopy.

Option: Single dose of postoperative intravesical chemotherapy.

INDEX PATIENT NO. 2: SMALL-VOLUME, LOW-GRADE Ta

Recommendation: Single dose of postoperative intravesical chemotherapy.

INDEX PATIENT NO. 3: MULTIFOCAL OR LARGE LOW-GRADE Ta, OR RECURRENT LOW-GRADE Ta

Recommendation: Intravesical BCG or MMC—goal to prevent/delay recurrence.

Option: Maintenance BCG or MMC.

INDEX PATIENT NO. 4: HIGH-GRADE Ta, T1, OR CIS

Standard: If T1 disease, but no muscularis in specimen, repeat resection.

Recommendation: Intravesical BCG with maintenance therapy.

Option: Consider cystectomy for select patients.

INDEX PATIENT NO. 5: HIGH-GRADE Ta, T1, AND/OR CIS AFTER PRIOR INTRAVESICAL THERAPY

Standard: T1 disease but no muscularis in specimen, repeat resection.

Recommendation: Consider cystectomy as therapeutic alternative.

Option: Further intravesical therapy may be considered.

BCG, bacille Calmette-Guérin; CIS, carcinoma in situ; MMC, mitomycin C.

From Hall MC, Chang SS, Dalbagni G, et al. Guideline for the management of non-muscle invasive bladder cancer (stages Ta, T1, and Tis): 2007 update. *J Urol* 2007;178(6):2314–30.

Lifestyle changes are particularly important because UC is directly linked to environmental factors in the majority of cases. **Smoking cessation, increased fluid intake, and a low-fat diet may all reduce the risk of recurrence**, with the former being of paramount importance. **Increased hydration reduces the concentration and dwell time of carcinogens** and thereby reduces the risk of malignant transformation within the urothelium (Jiang, 2008). The Physician Health Study showed an inverse correlation between fluid intake and the incidence of UC on longitudinal follow-up, but this simple measure may also be of benefit for secondary prevention for patients who already have a history of UC (Michaud et al, 1999). **High fat and cholesterol intake are now firmly established as risk factors** for many cancers, although the mechanisms are not as well defined as for other malignancies (Steineck et al, 1990).

A variety of agents have been investigated for chemoprevention strategies for patients with UC, including retinoids (i.e., vitamin A and its analogs) (Sporn et al, 1977; Becci et al, 1978; Eichholzer et al, 1996; Steinmaus et al, 2000), pyridoxine (vitamin B₆) (Byar and Blackard, 1977; Newling et al, 1995), α -tocopherol (Virtamo, 2000; Lotan et al, 2012), and difluoromethylornithine (DFMO) (Messing et al, 2005). However, none of these agents has proven useful in rigorous trials. Isoflavones were studied for the same purpose, but the studies were abandoned owing to higher bladder cancer risk in the patients consuming greater amounts of soy products (Sun, 2004).

The most promising data for secondary chemoprevention of UC relate to the use of high doses of multivitamins. One small study randomized 65 patients with noninvasive UC to either a recommended daily allowance (RDA) multivitamin or megadose vitamins with augmented levels of vitamins A, B₆, C, and E (Lamm et al, 1994). Comparison of the two regimens revealed no difference in recurrence rates in the first year; however, there was a statistically significant advantage for the megadose group when the 5-year recurrence rates were calculated. At that point, 80% of patients in the RDA group had experienced recurrence compared with only 40% in the megadose group. These findings suggest that the beneficial effect of megadose vitamins is related to their suppressive effect on partially transformed cells within the urothelium rather than inhibition of early recurrences, which are typically caused by tumor cell implantation or incomplete resection. Confirmation of these findings by larger prospective trials is necessary.

KEY POINTS: SURVEILLANCE AND PREVENTION

- Cystoscopy is the hallmark of surveillance. The optimum schedule is undefined but may be individualized on the basis of risk.
- Table 93-4 demonstrates reasonable surveillance protocols based on clinical scenarios. Guidelines for management are shown in Box 93-4.
- A number of tumor markers have shown the ability to improve the sensitivity of cytology, but specificity is lower for most.
- Increased fluids, smoking cessation, and a low-fat diet are recommended.

Prognostic Nomograms for Muscle-Invasive Bladder Cancer

Conclusions

CLINICAL PRESENTATION, DIAGNOSIS, AND EVALUATION

Bladder cancer has the fifth highest incidence of all malignancies in the United States, with an estimated 74,690 new cases and 15,580 deaths in 2014 (Siegel et al, 2014). Twenty percent to 30% of patients will present with muscle-invasive bladder cancer at the time of initial presentation. Despite aggressive therapy, a significant proportion of patients ultimately will experience recurrence and will die of their disease. Clinical understaging is not uncommon at the time of initial diagnosis with muscle-invasive disease, and therefore a multimodal therapeutic approach is often necessary to improve survival. A multidisciplinary approach is paramount to integrate appropriate therapy to individual patients, including surgery, systemic chemotherapy, and radiation therapy. This chapter reviews the evaluation and treatment of patients with muscle-invasive and metastatic bladder cancer.

Natural History

The majority of patients present with muscle-invasive disease at the time of initial presentation. A smaller subset (approximately 20%) will progress to muscle-invasive disease after an initial diagnosis of non-muscle-invasive bladder cancer. Muscle-invasive bladder cancer is a highly lethal entity and if left untreated will result in mortality within 2 years of diagnosis in 85% of cases (Prout et al, 1956). Additionally, some studies have shown worse outcomes for patients who progress from non-muscle-invasive disease; however, this is likely related to understaging of presumed noninvasive disease (Guzzo et al, 2009). Bladder cancer death after appropriate local therapy is typically the result of systemic disease; the majority of deaths occur within 2 years of initial treatment. Non-local-regional relapses are reflective of the presence of micrometastatic disease at the time of diagnosis and treatment and they continue to hamper long-term survival rates for patients with muscle-invasive disease. The significant risk of micrometastatic disease and our current inability to stage and to identify accurately patients with non-organ-confined disease before definitive local therapy continue to hamper pretreatment decisions and argue for a multidisciplinary treatment approach.

Histology

The majority of primary bladder cancers are urothelial carcinomas, representing more than 90% of all bladder tumors. Although squamous cell carcinoma comprises only approximately 5% of all bladder cancers in the Western world, it is more common in parts

of the Middle East and Africa secondary to endemic infection with schistosomal parasites, and it accounts for a significant percentage of bladder cancer histology in these regions (el-Mekresh et al, 2009). Squamous cell carcinoma histology in Western countries is more commonly associated with chronic urinary tract inflammation including patients with chronic indwelling catheters. Even rarer, adenocarcinomas represent roughly 2% of bladder cancers and can originate from either the urothelium or the urachus. Patients with bladder exstrophy are classically at an increased risk for bladder adenocarcinoma. Before definitive treatment it is important to rule out other more common sites of adenocarcinoma such as breast and colorectal sources. Standard treatment regardless of histologic subtype is radical cystectomy; however, timing of neoadjuvant chemotherapy and/or radiation therapy can vary by histologic subtype (Willis et al, 2013). Pure neuroendocrine variants of bladder cancer are relatively rare but highly aggressive, and they typically present at high pathologic stages or with metastatic disease (Mazzucchelli et al, 2009). Neuroendocrine features can also be seen with other histologic variants. Standard treatment for neuroendocrine bladder tumors includes neoadjuvant chemotherapy and radical cystectomy (Siefker-Radtke et al, 2004). Neuroendocrine tumors can be associated with paraneoplastic syndromes including ectopic adrenocorticotrophic hormone production, hypercalcemia, and hypophosphatemia. Carcinoid tumors, a type of neuroendocrine tumor, can also originate in the bladder. Large cell neuroendocrine tumors have also been reported and have a similar disease biology to that of small cell tumors (Akamatsu et al, 2008). Other rare histologic entities include rhabdomyosarcoma, leiomyosarcoma, and primary lymphoma.

Variant histologies of urothelial carcinoma also exist, including micropapillary, sarcomatoid, squamous, and glandular differentiation. Micropapillary tumors are aggressive and resemble papillary serous carcinoma of the ovary. There are conflicting reports regarding the responsiveness of micropapillary disease to neoadjuvant chemotherapy (Kamat et al, 2007; Ghoneim et al, 2011; Meeks et al, 2013). There is scant evidence to support treatment guidelines for many variant urothelial histologies; however, many of these subtypes are aggressive, and early definitive therapy should be considered. It is important to recognize variant histology to avoid diagnostic misinterpretations that could delay definitive care.

Clinical Staging

Clinical staging for bladder cancer is the assessment of disease extent before definitive treatment, whereas pathologic stage is determined by microscopic analysis of radical cystectomy and pelvic

TABLE 94-1 Incidence of Pathologic Pelvic Node Metastasis (%) at Radical Cystectomy in Selected Contemporary Series (2000-2012)

	NO. OF PATIENTS	P1	P2A	P2	P2B	P3A	P3	P3B	P4A	P4	P4B
Stein et al, 2001	1054	7		18		26		46	42		
Leissner et al, 2004	290	2	11		22	46		40	40		80
Vazina et al, 2004	176	4		16			40			50

Tarin et al, 2012	591	6		18				40		60	

lymphadenectomy specimens. Clinical staging for bladder cancer is determined by pathologic analysis of the depth of the invasion of the tumor on the transurethral resection (TUR) specimen, bimanual examination of the patient under anesthesia, liver function tests, chest radiography, and contrast-enhanced cross-sectional imaging of the abdomen and pelvis with upper tract imaging. Clinical understaging is not uncommon and contemporary cystectomy series demonstrate pathologic upstaging rates to be as high as 50% for patients with clinical T2 stage tumors (Table 94-1) (Svatek et al, 2011).

TUR is the gold standard method for establishing the diagnosis of muscle-invasive bladder cancer. In addition to pathologic staging, TUR also can provide valuable information on histologic variants that may direct therapeutic decision making. Although data are limited, a complete resection of macroscopic tumor is advisable when it is safe and feasible. Complete resection decreases local tumor burden and may optimize the response to neoadjuvant chemotherapy, or for patients undergoing chemoradiotherapy it may improve bladder preservation. Additionally, prospective randomized neoadjuvant chemotherapy trials have clearly demonstrated a significant survival benefit in patients who are pT0 at the time of radical cystectomy. This survival benefit (pT0 status) occurred regardless of whether neoadjuvant chemotherapy was administered, suggesting a potential benefit of aggressive TUR (Grossman et al, 2003b; Lavery et al, 2014). The status of the bladder neck in women and the prostatic urethra in men should also be carefully evaluated at the time of initial resection, as it can impact clinical decision making with regard to neoadjuvant chemotherapy (prostatic stromal invasion), surgical management of the urethra, and choice of urinary diversion at the time of radical cystectomy. Biopsies of the prostatic urethra may provide useful information in advance of radical cystectomy (Lerner et al, 2008). Using a resectoscope, a full loop of tissue is taken from the midprostate (or bladder neck in shorter prostates) to the mid- to distal verumontanum and 5 and 7 o'clock adjacent to the verumontanum. This is the site of the highest concentration of prostatic ducts and the area where carcinoma in situ (CIS) is most likely to be found (Sakamoto et al, 1993). The full-thickness prostatic resection allows the pathologist to evaluate the interface between the urethral mucosa, prostatic ducts, and stroma, which allows for accurate staging of the prostatic urethra (Wood et al, 1989). Negative prostatic urethral biopsies are associated with negative apical urethral margins and can replace the need for intraoperative frozen section at the time of radical cystectomy (Lerner and Shen, 2008). In women, bladder neck biopsies are an accurate surrogate for urethral biopsy when orthotopic urinary diversion is under consideration.

Bimanual examination under anesthesia remains an important aspect of primary tumor assessment. The examination is performed typically by placing the dominant hand on the suprapubic region and one or two fingers from the nondominant hand in the rectum (males) or vagina. Bimanual examination can be performed at the time of initial tumor resection and should be done before and after resection. The bimanual examination should be performed with the bladder drained and without a Foley catheter in place to maximize palpation of the bladder. Findings described originally by Marshall

are T2a: nonpalpable; T2b: induration but no three-dimensional mass; T3a: three-dimensional mass that is mobile; T4a: invading adjacent structures such as the prostate, vagina, or rectum; T4b: fixed to pelvic sidewall and not mobile (Marshall, 1952). Bimanual examination is not 100% accurate in predicting final tumor pathology, with an 11% clinical overstaging and a 31% clinical understaging rate reported (Ploeg et al, 2012).

Cross-sectional imaging plays an important adjuvant role to TUR and physical examination in the assessment and staging of the primary bladder tumor in patients with muscle-invasive disease. Abdominal and pelvic cross-sectional imaging are recommended by the National Comprehensive Cancer Network (NCCN) when muscle-invasive disease is suspected before TUR (NCCN guidelines Version 1, 2014). Studies vary widely on the overall sensitivity and specificity of computed tomography (CT) imaging with regard to final pathologic tumor stage at the time of radical cystectomy. Studies using multidetector CT scanners have reported the best results, with sensitivities ranging from 89% to 91% and specificities of 92% to 95% for local staging (Kim et al, 2004; Koplay et al, 2010). The timing of imaging is also important to note relative to TUR. Although it is optimal to obtain cross-sectional imaging before TUR, if imaging is obtained subsequently, it should be delayed approximately 7 days post-procedure to minimize inflammatory artifact, which can be mistaken for T3 disease (Kim et al, 2004). A high suspicion for extravesical disease is warranted when hydronephrosis is noted on cross-sectional imaging. The presence of hydronephrosis on staging CT is associated with an increased risk of extravesical disease (27.8% vs. 17.3%) at the time of cystectomy (Bartsch et al, 2007; Canter et al, 2008). The reported sensitivity and specificity of CT in detecting nodal metastasis ranges from 31% to 50% and 68% to 100%, respectively (Picchio et al, 2006; Baltaci et al, 2008; Lodde et al, 2010).

Magnetic resonance imaging (MRI) is generally considered to be more accurate than CT in detecting local tumor stage; however, reports vary in the literature. Rajesh and colleagues (2011) reported on 100 consecutive patients who underwent a 1.5-T MRI with gadolinium. The authors reported that the sensitivity and specificity of MRI in differentiating between organ-confined and non-organ-confined disease was 90.5% and 60%, respectively (Rajesh et al, 2011). Other studies have reported staging sensitivity ranging from 68% to 80% and specificity of 90% to 93%. MRI does appear to show an advantage over CT in predicting tumor stage, but is not particularly more accurate in detecting lymph node metastasis. Additionally, MRI has been reported as useful in predicting tumor grade and tumor chemosensitivity (Tuncbilek et al, 2009; Yoshida et al, 2012).

The usefulness of positron emission tomography and CT (PET/CT) in local staging of bladder cancer is limited as a result of the excretion of standard PET (^{18}F -fluorodeoxyglucose) into the urine. Although PET/CT has not proven of superior benefit to that of CT alone for local staging, some studies have demonstrated its superiority with regard to nodal staging. The reported sensitivity and specificity of PET/CT in detecting nodal metastasis ranges from 57% to 81% and 88% to 100%, respectively (Drieskens et al, 2005; Kibel et al, 2009; Apolo et al, 2010; Lodde et al, 2010).

Pathologic Staging

The American Joint Committee on Cancer (AJCC) tumor, node, metastases (TNM) system is the most commonly used method for staging bladder cancer (Table 94-2) and can be used for staging

TABLE 94-2 Tumor Node Metastasis Staging System for Bladder Cancer

PRIMARY TUMOR (T)

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Noninvasive papillary carcinoma
Tis	Carcinoma in situ: “flat tumor”
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades muscularis propria
pT2a	Tumor invades superficial muscularis propria (inner half)
pT2b	Tumor invades deep muscularis propria (outer half)
T3	Tumor invades perivesical tissue
pT3a	Microscopically
pT3b	Macroscopically (extravesical mass)
T4	Tumor invades any of the following: prostatic stroma, seminal vesicles, uterus, vagina, pelvic wall, abdominal wall
T4a	Tumor invades prostatic stroma, uterus, vagina
T4b	Tumor invades pelvic wall, abdominal wall

REGIONAL LYMPH NODES (N)*

Nx	Lymph nodes cannot be assessed
N0	No lymph node metastasis
N1	Single regional lymph node metastasis in the true pelvis (hypogastric, obturator, external iliac, or presacral lymph node)
N2	Multiple regional lymph node metastasis in the true pelvic (hypogastric, obturator, external iliac, or presacral lymph node metastasis)
N3	Lymph node metastasis to the common iliac lymph nodes

DISTANT METASTASIS (M)

M0	No distant metastasis
M1	Distant metastasis

ANATOMIC STAGE/PROGNOSTIC GROUPS

Stage 0a	Ta	N0	M0
Stage 0is	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2a	N0	M0
	T2b	N0	M0
Stage III	T3a	N0	M0
	T3b	N0	M0
	T4a	N0	M0
Stage IV	T4b	N0	M0
	Any T	N1-3	M0
	Any T	Any N	M1

Note: cTNM is the clinical classification, and pTNM is the pathologic classification.

*Regional lymph nodes include both primary and secondary drainage regions. All other nodes above the aortic bifurcation are considered distant lymph nodes.

From Edge SB, Byrd DR, Compton CC, et al, editors. AJCC cancer staging manual. 7th ed. New York: Springer; 2010.

patients clinically and pathologically. T staging follows a stepwise fashion based on depth of tumor penetration. As with other tumors, N and M stages refer to the presence of regional nodal and distant metastasis, respectively. The prognostic value of T2 and T3 substaging has been widely debated and reported. A multicenter series of 565 radical cystectomy patients with pT2, node-negative disease demonstrated improved recurrence-free (73.2% vs. 58.7%) and cancer-specific survival (78.0% vs. 65.1%) for pT2a and pT2b disease, validating this subgrouping (Tilki et al, 2010a). The prognostic usefulness of the pT3 subgrouping was also reported in the same cohort of radical cystectomy patients. Of the 356 pT3N0 patients, pT3b substaging was associated with worse recurrence-free (60.7% vs. 47.9%) and cancer-specific survival (64.4% vs. 55.0%) at 5 years (Tilki et al, 2010b). The T4a prostate designation requires established stromal invasion, which can occur via the urethra or as a direct extension via the bladder neck or posteriorly into the seminal vesicles or periprostatic ducts. CIS in the prostatic urethra or ducts does not represent upstaging because outcome is determined by the primary bladder cancer stage (Esrig et al, 1996; Pagano et al, 1996). Lymph node staging is illustrated in Table 94-2; positive nodes above the common iliac artery are considered N+M1 disease. Pathologically, organ-confined bladder cancer is considered to be pT2bN0M0 or less at the time of cystectomy (Soloway et al, 2012).

RADICAL CYSTECTOMY AND PELVIC LYMPH NODE DISSECTION FOR MUSCLE-INVASIVE BLADDER CANCER

For patients with clinical T2-T4a, N0, M0 disease, radical cystectomy and bilateral pelvic lymph node dissection remains the gold standard therapy by which all other treatment modalities should be compared. Radical cystectomy provides excellent local control with pelvic recurrence rates as low as 4% in patients with node-negative disease (Morris et al, 2009). Randomized trial data have demonstrated superior outcomes with neoadjuvant systemic chemotherapy, which will be further discussed in subsequent sections.

Time from initial diagnosis of muscle invasion to cystectomy likely impacts oncologic outcomes, particularly if there is a delay of greater than 12 weeks. Sanchez-Ortiz and colleagues (2003) initially published this observation in their cohort of 290 cystectomy patients noting a higher proportion of extravesical tumors, nodal metastasis, and worse survival in patients in which cystectomy was delayed more than 12 weeks. Since that observation was published, multiple studies have demonstrated similar results (Chang et al, 2003; Lee et al, 2006b; Gore et al, 2009). Lee and associates (2006b) reported worse disease-specific and overall survival rates for patients with muscle-invasive disease who underwent radical cystectomy more than 3 months after initial diagnosis. Administrative data sets have also provided similar findings. Of 441 patients who underwent radical cystectomy from 1992 to 2001 in the Surveillance, Epidemiology, and End Results (SEER) database, a delay in surgery of more than 12 weeks and 24 weeks resulted in a twofold increase in disease-specific and overall mortality compared to more timely surgical intervention (Gore et al, 2009). Similar results have been noted in other radical cystectomy cohorts (Ayres et al, 2008; Fahmy et al, 2008; Kulkarni et al, 2009). Although it is difficult to say with certainty, based on retrospective surgical cohorts, exactly how expeditiously surgery should be performed, a significant delay does appear to be detrimental to oncologic outcomes.

In men, radical cystectomy includes excision of the surrounding perivesical soft tissue, prostate, and seminal vesicles, and, in women, it includes the ovaries, uterus with cervix, and anterior vagina. Since the mid-2000s, greater emphasis has been placed on urinary and sexual quality of life following cystectomy. This has led to a greater interest in organ preservation in both men and women. In men, preservation of the neurovascular bundles, some or all of the prostate, and the seminal vesicles have been reported in an attempt to

improve postoperative quality of life. The majority of reports is limited to small retrospective cohorts and must be analyzed within the context of such limitations. It is also important for the surgeon to weigh the oncologic risk of organ preservation relative to that of cancer recurrence. For instance, prostate cancer can be present in upward of 23% to 54% of radical cystoprostatectomy specimens with up to a third having clinically significant disease (Abdelhady et al, 2007; Pettus et al, 2008). Additionally, the significant incidence of urothelial carcinoma involving the prostate (17% to 75%) noted on complete radical cystoprostatectomy specimens is an obvious oncologic limitation with this technique (Ayyathurai et al, 2007; Pettus et al, 2008; Revelo et al, 2008; Richards et al, 2010; Arce et al, 2011; Tabibi et al, 2011). If prostatic preservation is considered, transurethral sampling of the prostatic urethra and bladder neck is advisable to maximize appropriate patient selection. Other reported preoperative features associated with prostatic urethral involvement include the presence of tumor at the bladder neck (Pettus et al, 2008; Richards et al, 2010; Abdelsalam et al, 2011; Arce et al, 2011), tumor multifocality (Nixon et al, 2002; Kefer et al, 2008), and the presence of CIS (Kefer et al, 2008; Richards et al, 2010; Arce et al, 2011). Functional outcomes following prostate preservation tend to be directly associated with the amount of tissue spared at the time of surgery. Davila and coworkers (2007) reported on a small number of patients undergoing either apical ($n = 15$) or total prostate-sparing cystectomy ($n = 6$). Using the erectile function domain score of the International Index of Erectile Function (IIEF) questionnaire, the authors reported mild erectile dysfunction in the apical-sparing group. Also using an apical-sparing technique, Wunderlich and associates reported a 94% day and nighttime continence rate with 87% of patients achieving baseline erectile function following surgery (Wunderlich et al, 2006). Posterior sparing (posterior prostate and seminal vesicles) was also reported by several authors with limited numbers of patients. Using this technique, excellent outcomes with regard to continence and erectile function have been reported (Spitz et al, 1999; Girgin et al, 2006). Finally, total prostate sparing has also been described in several series of patients. Nieuwenhuijzen and coworkers (2008) reported outcomes of 41 patients who underwent total prostate sparing at the time of radical cystectomy and they noted 95% and 74% day and nighttime continence rates, respectively. However, 12 patients did require long-term clean intermittent catheterization because of an inability to empty volitionally. Erectile function was maintained in 78% of patients who were functioning preoperatively. Although organ preservation has the potential to improve overall quality of life, radical cystoprostatectomy remains the gold standard.

Preservation of the uterus, ovaries, and vagina has also been explored in women at the time of radical cystectomy. Although an anterior exenteration has classically been advocated in women at the time of radical cystectomy, urothelial carcinoma rarely involves the gynecologic organs with an overall incidence of approximately 5% of cases (Chang et al, 2002). Unless there is tumor involvement of the bladder neck, a complete urethrectomy can be omitted at the time of cystectomy allowing for orthotopic bladder substitution in women. Additionally, carefully selected patients can also forgo removal of the uterus and anterior vagina, which potentially allows for better anatomic support for a neobladder and preserves the autonomous nerves.

Bilateral Pelvic Lymph Node Dissection

A meticulous pelvic lymph node dissection is an essential component of radical cystectomy. It is well established that approximately 25% of patients will have pathologic lymph node metastases at the time of cystectomy (Lerner et al, 1993), and lymph node status is the most powerful surrogate for long-term recurrence-free and overall survival following radical cystectomy (Poulsen et al, 1998; Stein et al, 2001). The value of a meticulous pelvic lymph node dissection was first reported by Skinner and coworkers (1982), demonstrating better local control rates, potential for cure, and acceptable morbidity in patients undergoing radical cystectomy. Since that initial report, multiple surgical series have demonstrated

the profound impact of nodal involvement at the time of radical cystectomy with approximately 70% to 80% of patients with lymph node metastasis ultimately experiencing disease recurrence in contrast to approximately 30% of patients with a negative pelvic lymph node dissection (Shariat et al, 2006b; Stamatakis et al, 2012). The extent of lymph node dissection at the time of cystectomy has been shown as an independent predictor of survival and local recurrence even when chemotherapy status and other pathologic factors are controlled (Herr et al, 2004). Whereas the importance of a lymph node dissection seems undebatable, what actually constitutes an adequate lymph node dissection and its exact therapeutic benefit remains less clear.

Anatomic Extent of Pelvic Lymph Node Dissection and Landing Zones

The primary lymphatic drainage site for bladder cancer includes the internal iliac, external iliac, obturator, and presacral lymph nodes. Secondary drainage sites include higher echelon nodes, including the common iliac, para-aortic, interaortocaval, and paracaval lymph nodes (Abol-Enein et al, 2004; Leissner et al, 2004; Vazina et al, 2004). Although multiple studies have demonstrated that an extended pelvic lymph node dissection offers improved prognostic staging, the exact anatomic extent of dissection remains somewhat controversial. The cranial extent of an adequate lymph node dissection varies across cystectomy series ranging from the crossing of the ureter at the level of the common iliac vessels to as high as above the aortic bifurcation at the level of the inferior mesenteric artery (Poulsen et al, 1998; Mills et al, 2001; Abol-Enein et al, 2004; Leissner et al, 2004).

Multiple surgical series have evaluated the anatomic extent and distribution of nodal metastasis at the time of cystectomy. Abol-Enein and colleagues in Mansoura, Egypt, evaluated the extent and distribution of positive lymph nodes in 200 consecutive patients who underwent radical cystectomy at a single institution over a 4-year period (Abol-Enein et al, 2004). The anatomic extent of the lymph node dissection was the inferior mesenteric artery superiorly in all patients. Twenty-four percent of patients exhibited nodal disease, with a mean number of eight positive lymph nodes. In 22 patients only a single lymph node was positive, of which 21 were located in the endopelvis. Metastasis outside of the true pelvis was only found in multinodal disease and was associated with involvement of the obturator and/or iliac nodes in all cases. The authors found no evidence of "skip" metastasis in patients with positive nodes. The authors suggested that the obturator and internal iliac nodes represent the sentinel lymphatic drainage areas and that if lymphadenectomy proved to be negative on frozen-section analysis at the time of surgery, a more superior dissection was not warranted. Similarly, the Memorial Sloan Kettering Cancer Center (MSKCC) group has reported on the anatomic extent and spread of lymph node metastasis (Bochner et al, 2004). The authors reported on 144 patients who underwent either a standard or extended pelvic lymph node dissection at the time of radical cystectomy. A standard pelvic lymph node dissection was defined superiorly by the iliac bifurcation and included the external iliac, hypogastric, and obturator lymph node packets. An extended dissection also included the nodal packets to the level of the aortic bifurcation to no more than 2 cm proximal to the bifurcation. The common iliac and presacral nodes were also included in the extended dissection template. As one would expect, the absolute number of positive nodes was significantly higher in the extended lymph node dissection group (22.5 vs. 8). However, there was not a staging advantage noted in the extended lymph node group, with both dissections yielding the same percentage of patients with positive lymph nodes (21%). Four percent of patients presented with positive lymph nodes identified within the para-aortic packets, all of which also showed positive lymph nodes in lower dissection packets. The authors did note four patients with micrometastatic disease to the common iliac vessels only, concluding that this area should be considered part of the standard lymph node dissection.

Although “skip” metastasis appears to be a relatively rare event in bladder cancer, it has been reported in the literature. A prospective multicenter study of 290 patients undergoing radical cystectomy with extended pelvic lymphadenectomy reported nodal metastasis in 27.9% of patients (Leissner et al, 2004). The authors reported lymph node metastasis based on three defined anatomic regions. Level 1 included lymph nodes below the common iliac bifurcation, level 2 included lymph nodes above the common iliac bifurcation but below the aortic bifurcation, and level 3 included lymph nodes to the level of the inferior mesenteric artery. Although no skip lesions were noted above the level of the aortic bifurcation, 6.9% of patients had nodal metastasis in level 2. Tarin and colleagues (2012) reported their lymph node dissection findings in 591 patients undergoing a radical cystectomy during a 10-year period, of which 19% exhibited positive nodes. The authors reported 6% of patients with skip lesions above the common iliac bifurcation with no positive nodes in the true pelvis. Finally, Vazina and associates (2004) also reported one patient with lymph node metastases at or above the aortic bifurcation or common iliac region without nodal involvement of more distal sites in their series of 176 radical cystectomy patients.

The anatomic extent of the pelvic lymph node dissection has also been evaluated in multiple series with regard to oncologic outcome. Dhar and colleagues (2008) reported on two consecutive series of patients from the Cleveland Clinic and the University of Bern, totaling 658 patients who either underwent a limited or an extended pelvic lymph node dissection. The limited node dissection included the pelvic sidewall between the genitofemoral and obturator nerves, and the bifurcation of the iliac vessels to the circumflex iliac vein. The extended dissection extended cephalad to the crossing of the ureters with the common iliac arteries and removal of all tissue along the lateral and medial portion of the internal iliac vessels. The overall proportion of lymph node positive patients in the extended versus limited cohorts was 26% and 13%, respectively. The 5-year recurrence-free survival of patients with lymph node positive disease was 7% for limited and 35% for extended node dissection. The 5-year recurrence-free survival for pT2pN0 cases was 67% and 77% for limited and extended dissections, respectively, and 23% and 57% for pT3N0 cases, respectively. The 5-year recurrence-free survival for pT2pN0-2 cases was 63% and 71%, respectively, for limited and extended lymph node dissections and 19% and 49%, respectively, for pT3pN0-2 patients. This study, in a large cohort of patients, confirms the value of an extended pelvic lymph node dissection with regard to staging accuracy and prognosis.

Based on the anatomic mapping studies described previously, it is recommended that an adequate pelvic lymph node dissection for bladder cancer at a minimum includes all lymphatic tissue around the common iliac, intercommon iliac, internal iliac, and obturator packets bilaterally. It has also been suggested that frozen-section analysis be performed for the lymph nodes in the true pelvis, and if metastasis is not identified, a more superior dissection can be omitted.

Number of Lymph Nodes Removed at the Time of Cystectomy

Multiple retrospective surgical series have attempted to quantify the minimum number of lymph nodes that constitutes an adequate pelvic lymph node dissection (Leissner et al, 2000; Bochner et al, 2001; Herr, 2003; Stein et al, 2003). Although controversy remains regarding the actual number of nodes that constitutes an adequate dissection, the absolute number of nodes removed has been shown to provide important prognostic information and staging accuracy both in lymph node positive and lymph node negative patients.

As one would expect, increasing nodal yield at the time of pelvic lymph node dissection improves the sensitivity of detecting nodal metastasis. Using a multi-institutional cohort, Capitanio and colleagues (2009) evaluated the probability of finding lymph node positive disease at the time of cystectomy based on the total number

Figure 94-1. A plot describing the relationship between the number of lymph nodes removed and the probability of detecting lymph node metastasis. (From Capitanio U, Suardi N, Shariat SF, et al. Assessing the minimum number of lymph nodes needed at radical cystectomy in patients with bladder cancer. *BJU Int* 2009;103:1359–62.)

of lymph nodes removed. Of the 731 patients included in this study, 23.8% had positive nodes. Using receiver operating characteristic curves, the authors predicted a 75% chance of identifying one or more lymph node metastases if 25 nodes were removed. This probability improved to 90% with 45 nodes and decreased to 50% if 15 to 25 nodes were removed, suggesting a 25-node minimum as a reasonable cut-off to adequately stage and detect lymph node metastasis (Fig. 94-1).

In addition to staging, lymph node count has been reported to improve therapeutic efficacy; however, prospective data to substantiate such a benefit are currently lacking. Leissner and colleagues (2000) retrospectively analyzed outcomes in 447 cystectomy patients in Mainz, Germany. Using a 16-node threshold, there were significant differences in cancer-specific and disease-free survival among patients with 16 or more lymph nodes removed compared to those with fewer nodes removed. For their survival analysis, a 16 lymph node threshold was used because the correlation between the total number of lymph nodes removed and the percentage of positive nodes was strongest at this count. There is no general consensus in the literature regarding the exact threshold of nodes at which a survival benefit can be predicted, with most studies reporting numbers in the 9 to 16 range (Leissner et al, 2000; Herr et al, 2002; Herr, 2003; Konety et al, 2003; Stein et al, 2003; Hollenbeck et al, 2008; May et al, 2011). Koppie and colleagues (2006) from the MSKCC group reported a study designed to determine if there is a minimum number of lymph nodes analyzed, above which there is no improvement in survival. The study included 1121 patients who underwent radical cystectomy during a 14-year period. The authors were unable to find a plateau in the dose-response curve with an increasing number of nodes up to 23; however, few patients had more than 24 nodes removed. Limitations of this study include the fact that 13% of patients had no nodes identified on the pathology report and the percent of patients who underwent an extended node dissection was not reported.

Although the studies in the last two sections have demonstrated the prognostic and therapeutic value of a thorough pelvic lymph node dissection at the time of radical cystectomy, it must be remembered that they are all either retrospective or nonrandomized

reports. There are inherent biases that need to be accounted for when considering the actual value and extent of a pelvic lymph node dissection when one considers it from a nonprospective, non-randomized approach. Surgical and nonsurgical factors, including anatomic extent of the template and pathologic processing, including the number of packets submitted to pathology, can greatly influence nodal counts (Bochner et al, 2001; Stein et al, 2007a; Ather et al, 2008; Kulkarni et al, 2008; Fang et al, 2010). More definitive studies are currently underway to address this issue better, including two randomized controlled trials, one in the United States and one in Europe, with the goal of determining the importance and extent of lymph node dissection at the time of radical cystectomy.

Lymph Node Density and Extracapsular Nodal Extension

Lymph node density refers to the percentage of positive nodes relative to the total number of nodes removed (Kassouf et al, 2008). Studies regarding the impact of lymph node density on prognosis have been mixed. Stein and colleagues (2003) first described the concept of lymph node density in bladder cancer. In their study of node-positive bladder cancer patients, they identified a lymph node density of 20% to carry prognostic value. Herr (2003) and colleagues have also demonstrated the 20% lymph node density value to confer prognostic value. In their study of 162 patients with lymph node positive bladder cancer patients who had a lymph node density of less than 20%, these patients experienced a significantly better 5-year disease-specific survival following radical cystectomy. Similarly, Guzzo and colleagues (2010) reported the outcomes of 85 node-positive patients following radical cystectomy, and they found that lymph node density less than 20% predicted a more favorable response to adjuvant chemotherapy. Conversely, Tarin and colleagues (2012) could not demonstrate an association between lymph node density compared to that of lymph node status alone in 591 radical cystectomy patients who underwent extended lymphadenectomy. A similar study by Jensen and colleagues of 167 radical cystectomy patients echoed these findings (Jensen et al, 2012). The current lymph node density studies reported in the literature are retrospective surgical series, and they report varying lymph node counts and templates of dissection, in turn limiting comparisons between studies.

Several small retrospective series have reported the potential prognostic significance of extranodal extension. Fajkovic and colleagues (2013) evaluated extranodal extension in 748 node-positive bladder cancer cases treated with cystectomy at several centers. A total of 375 (50%) presented with extranodal extension. Using a multivariable model, including pT stage, tumor grade, age, gender, lymphovascular invasion, surgical margin status, lymph node density, total lymph nodes, number of positive nodes, and adjuvant therapy, extranodal extension was significantly associated with both disease recurrence and cancer-specific mortality. Similarly, Seiler and colleagues (2011) reported an extranodal extension to be an independent predictor of overall survival and disease-specific survival in a smaller cohort (n = 162) of lymph node positive patients.

Intraoperative Decision Making

Grossly Positive Nodes and T4b Disease

The management of patients with grossly involved lymph nodes includes treatment of systemic micrometastatic disease and locoregional disease. If disease is recognized on preoperative imaging and outside the true pelvis, a CT-guided biopsy can be performed to confirm histology. If it is positive, then chemotherapy should be initiated followed by radical cystectomy. If adenopathy is encountered at the time of cystectomy, a frozen section should be taken to confirm metastasis, and an extended lymph node dissection and radical cystectomy should be completed when feasible. Cystectomy is not performed when lymph node metastases are unresectable because of bulk, when there is evidence of extensive periureteral disease, when the bladder is fixed to the pelvic sidewall, or when

the tumor is invading the rectosigmoid colon. Not surprisingly, if radical cystectomy is aborted, patient prognosis is poor. The Johns Hopkins group published their outcomes of 35 patients who had an aborted cystectomy because of intraoperative findings of metastatic disease (Guzzo et al, 2008). Sixty percent of patients in the study cohort died from disease progression at a median time of 26 months. Similarly, Yafi and colleagues (2011) reported outcomes on 31 patients in which cystectomy was aborted for unresectable disease. The 2-year and 5-year overall survival in this cohort of patients was 41% and 0%, respectively.

Intraoperative Frozen Sections of the Ureter

The incidence of involvement of the distal ureter with tumor on final pathology at the time of radical cystectomy was 6% to 8% (Sharma et al, 1970; Gakis et al, 2011). There is not a definitive recommendation for the precise length of the distal ureter that should be removed at the time of surgery. Final ureteral margin status has proven to be an independent predictor of upper tract recurrence following cystectomy (Tran et al, 2008; Volkmer et al, 2009). However, the overall incidence of upper tract recurrence following cystectomy is a relatively rare event ranging from 2% to 8% (Schumacher et al, 2006; Tran et al, 2008; Giannarini et al, 2010; Gakis et al, 2011). There are several risk factors for upper tract recurrence following cystectomy including bladder CIS, distal ureteral involvement with tumor, and high-grade pTa-T1 disease (Volkmer et al, 2009). Upper tract recurrences have been reported to recur most commonly between 2 and 4 years postcystectomy (Meissner et al, 2007; Sanderson et al, 2007; Wagner et al, 2008). Unfortunately, when upper tract recurrences do occur they are often locally advanced and can be associated with worse outcomes than de novo upper tract disease (Balaji et al, 1999; Sved et al, 2004; Sanderson et al, 2007). The risk of upper urinary tract recurrence appears to be a stable event with time (Tran et al, 2008).

The role of intraoperative frozen-section analysis of the ureters at the time of cystectomy remains somewhat controversial. Although it would seem intuitive that achieving a negative ureteral margin is necessary, the literature has not always demonstrated improved outcomes with this approach (Schoenberg et al, 1996; Silver et al, 1997; Lee et al, 2006a; Osman et al, 2007). Contemporary studies report frozen-section analysis of the distal ureteral margins to have a 74% to 75% sensitivity, a 98% to 99% specificity, and a positive predictive value of 98% (Raj et al, 2006; Gakis et al, 2011). Whether or not sequential resection for positive frozen ureteral margins confers an absolute benefit remains questionable. An analysis of 1397 cystectomy patients who underwent frozen-section analysis of the distal ureters demonstrated an initial positive margin rate of 12.7% (Tollefson et al, 2010). In those with initial positive margins, 83% were subsequently converted to a negative margin with further resection. Interestingly, those with an initial positive margin but negative final margin still were at higher risk for upper tract recurrence (hazard ratio [HR] = 4.88, 95% confidence interval [CI] 3.02 to 7.90, $P < .001$) compared to those with initial negative margins. This risk was intermediate to that of those with positive final margins (HR = 7.37, 95% CI 4.3 to 16.44, $P < .001$). These findings suggest patients with ureteral disease at the time of cystectomy experience an increased risk of upper tract recurrence regardless of margin status, but this risk can be at least partially mitigated by achieving a negative margin. The impact of ureteral skip lesions has also been reported. Investigators from the University of Texas MD Anderson Cancer Center evaluated 660 radical cystectomy patients who had both a distal frozen and final proximal ureteral margin (Hoang et al, 2014). Ureteric skip lesions (negative distal frozen, positive proximal permanent margin) were identified in 4.8% of patients with CIS, which is the most common skip lesion (55.9% of cases). Skip lesions were associated with lower median overall survival in patients with pT0 or pTa disease.

Given the findings outlined earlier, it appears logical to attempt to clear the distal ureter when feasible at the time of radical cystectomy. When frank tumor is encountered, it should be resected to a negative margin. When CIS only is encountered, maximal resection

without compromising ureteral length for urinary diversion is advocated, as it is debatable whether a negative CIS margin reduces upper tract recurrence or is definitively associated with a worse outcome (Lee et al, 2006a; Raj et al, 2006). In patients who are at high risk for an upper tract recurrence, ureteropyeloscopy, when feasible, is the most sensitive means for detecting upper tract recurrences.

Prostatic Urothelial Carcinoma and Management of the Distal Urethra

The absolute risk of urethral recurrence following cystectomy ranges from 4% to 8% in men (Nieder et al, 2004; Varol et al, 2004; Stein et al, 2005; Huguet et al, 2008; Nelles et al, 2008; Cho et al, 2009). The majority of urethral recurrences are symptomatic, but in patients who are deemed at high risk for such events, periodic cytology can be useful for detection of recurrences (Clark et al, 2004; Huguet et al, 2008). Risk factors for urethral recurrence include non-muscle-invasive disease on final pathology and prostatic urethral involvement (Stein et al, 2005; Huguet et al, 2008). The extent of prostatic involvement is also predictive of urethral recurrence. Prostatic stromal invasion is associated with the highest risk (as high as 30%) compared to that of prostatic urethral CIS and ductal or acinar involvement (Hardeman, 1990). Urethrectomy should be considered in men with diffuse CIS of the prostatic urethra or ducts or if there is prostatic stromal invasion. Preoperative evaluation of the prostatic urethra via biopsy can be performed to characterize further the risk of urethral recurrence and help dictate intraoperative management of the distal urethra and choice of urinary diversion. The sensitivity and specificity of transurethral prostatic urethral biopsy is moderate with a relatively low positive predicate value compared to final cystoprostatectomy specimens (Donat et al, 2001). Given the modest value of preoperative urethral biopsy, some experts advocate for urethrectomy only in the setting of a positive apical urethral margin (Donat et al, 2001; Stein et al, 2005). Small low-grade papillary tumors of the urethra can be resected before cystectomy and the urethra retained if there is no other indication for urethrectomy. Of note, several retrospective surgical series have reported a decreased risk of urethral recurrence in patients with orthotopic urinary diversions (Hassan et al, 2004; Nieder et al, 2004; Stein et al, 2005). Whereas some have hypothesized that this decrease may be related to a protective effect of exposing the urethra to urine, it is more likely a result of selection bias.

Managing the Female Urethra

Before female orthotopic bladder substitution became more commonplace, complete removal of the female urethra at the time of radical cystectomy was routine. T4 tumors involving the urethra and/or vagina mandate complete urethrectomy, and these patients should not be offered urethral preservation. Concomitant involvement of the urethra in women with bladder cancer ranges from 2% to 12% (Stenzl et al, 1995; Stein et al, 2007b). Clinical features associated with an increased risk of distal urethral tumor

involvement include primary tumor location at the bladder neck, vaginal involvement, or inguinal lymphadenopathy (Stein et al, 1995; Maralani et al, 1997; Stein et al, 1998). Although tumor presence at the bladder neck is significantly associated with urethral involvement, approximately 60% of patients with tumors in this location will not have a tumor in the urethra on final pathology and therefore controversy exists with regard to an absolute need for complete urethrectomy in this setting. Frozen-section analysis of the distal urethra has demonstrated high correlation with final urethral margin and should be performed in all women in which orthotopic bladder substitution is being considered (Stein et al, 1998; Akkad et al, 2006). Isolated urethral recurrence following orthotopic bladder substitution occurs in approximately 1% of cases (Ali-El-Dein et al, 2009; Stein et al, 2009).

Oncologic Outcomes following Radical Cystectomy

Table 94-3 illustrates the reported oncologic outcomes of large surgical series. Pathologic tumor stage and presence of nodal metastasis are the strongest predictors of recurrence and survival following cystectomy (Frazier et al, 1993; Stein et al, 2001; Madersbacher et al, 2003; Hautmann et al, 2006; Shariat et al, 2006b; Ghoneim et al, 2008; Manoharan et al, 2009). Patients who are pT0 or who have residual noninvasive disease on final pathology have excellent outcomes with 5-year cancer-specific survival rates approaching 90% (Stein et al, 2001; Ghoneim et al, 2008). Patients with pT2 tumors have 5-year disease-specific survival rates ranging from 70% to 81%. Pathologic T2 substratification has been shown in multiple studies to confer prognostic value with regard to recurrence-free and disease-specific survival (Bastian et al, 2008; Ghoneim et al, 2008; Tilki et al, 2010a). The presence of non-organ-confined disease (>pT2) is a strong predictor of outcome. Pathologic T3 patients fare significantly worse with 5-year disease-specific survival rates ranging from 40% to 52%. The prognostic value of pT3 substaging has been debated in the literature. Two large multicenter surgical series have reported a prognostic discrimination between pT3a and pT3b, with node-negative patients reporting an improved recurrence-free and disease-specific survival advantage in pT3a patients (Tilki et al, 2010b; Sonpavde et al, 2011). However, pT3 substaging has not demonstrated improved stratification in node-positive patients (Quek et al, 2004). Lymph node status appears to be the single greatest predictor of disease outcome. Node-positive disease confers a poor prognosis with 5-year disease-specific survival rates ranging from 21% to 35%. However, long-term survival has been reported in patients with low-volume lymph node metastasis (Steven et al, 2007; Dhar et al, 2008; Bruins et al, 2009; Rink et al, 2013).

Margin status is also an important predictor of recurrence following radical cystectomy (Dotan et al, 2007; Novara et al, 2010). A multicenter, retrospective study of 4410 radical cystectomy patients reported an overall soft tissue positive margin rate of 6.3% (Novara et al, 2010). A positive soft tissue margin was associated with a significantly increased risk of disease recurrence (HR = 1.52, $P < .001$) and cancer-specific mortality (HR = 1.51, $P < .001$). Additional variables that were reported to possess prognostic value following radical cystectomy include the presence of lymphovascular invasion (Lotan et al, 2005; Herrmann et al, 2008; Shariat et al, 2010),

TABLE 94-3 Percentage of 5-Year Disease-Specific Survival (DSS) by Pathologic Stage after Radical Cystectomy with and without Pelvic Lymph Node Metastasis: Selected Series Reporting DSS (2000-2012)

SELECTED SERIES	NO. OF PATIENTS	≤P1	P2A	P2	P2B	P3A	P3	P3B	P4A,B	N NEG	N+
Stein et al, 2001	1054	88		81		68		47	44	78	35
Madersbacher et al, 2003	507	76		74			52		36	—	33
Hautmann et al, 2006	788	90		72			43		28	75	21
Shariat et al, 2006b	888	81		72			44		28	80	35
Ghoneim et al, 2008	2720	82	75		53		40		29	62	27

molecular markers (Youssef et al, 2011; Shariat et al, 2014), surgical expertise and hospital volume (Konety et al, 2005), body mass index (Bagrodia et al, 2009), and age (Hollenbeck et al, 2004; Nielsen et al, 2007). Despite aggressive surgical therapy, approximately 50% of cystectomy patients will ultimately die of disease. Recurrence of disease often occurs within the first 2 years following surgery, with median recurrence times of 7 to 18 months reported in large series.

NEOADJUVANT CHEMOTHERAPY FOR MUSCLE-INVASIVE BLADDER CANCER

Nearly 50% of patients with muscle-invasive bladder cancer treated with cystectomy alone will progress to metastatic disease (Stein et al, 2001; Ghoneim et al, 2008). Clearly, surgery alone is not sufficient therapy in a large number of patients with invasive bladder cancer. Systemic therapy with cisplatin-based chemotherapy has been shown to provide response rates in multiple bladder cancer studies since the mid-1980s (Sternberg et al, 1985; Stenzl et al, 2009). Since the initial reports of its usefulness in muscle-invasive bladder cancer, there have been multiple randomized controlled studies undertaken to define further the effectiveness of neoadjuvant cisplatin-based chemotherapy in advance of cystectomy. Unfortunately, many of these studies have been hampered by inadequate power and a lack of standardization of surgical approaches to demonstrate clearly a survival advantage with neoadjuvant chemotherapy in most of these studies when they are evaluated individually.

There are several arguments for cisplatin-based chemotherapy in the neoadjuvant setting for patients with muscle-invasive bladder cancer. First, systemic chemotherapy is often better tolerated before surgery, rather than after surgery when patients may experience a delay in chemotherapy administration because of complications or debilitation. Second, patients who present with micrometastatic disease will receive therapy in a more timely fashion when their burden of disease is potentially low. Third, neoadjuvant chemotherapy has the potential to downstage bulky and locally advanced tumors, allowing for a higher likelihood for negative surgical margins that are a known predictor of local recurrence following cystectomy. Finally, neoadjuvant chemotherapy allows the clinician to assess each individual's response to therapy. A disadvantage of neoadjuvant chemotherapy is a delay in definitive local therapy for patients who do not respond to chemotherapy and thus experience disease progression.

The European Organization for Research and Treatment of Cancer (EORTC) and the Medical Research Council (MRC) performed the largest neoadjuvant chemotherapy trial in bladder cancer. This study evaluated the benefit of 3 cycles of neoadjuvant cisplatin, methotrexate, and vinblastine in 976 patients before radiation or cystectomy (International Collaboration of Trialists, 1999). The study was designed to detect an absolute improvement in survival of 10% with a power of 90% and a type 1 error of 5%. Eighty percent of the 491 patients who were assigned to the chemotherapy arm completed 3 cycles. The study was performed at 106 centers and the decision as to whether patients received radiation or cystectomy was at the discretion of the investigators. Chemotherapy-related mortality was reported to be 1%. At the time of the initial analysis there was a trend noted toward improved survival in the neoadjuvant chemotherapy arm (HR = 0.85, 95% CI 0.71 to 1.02; $P = .075$) with a median follow-up of 4 years. This translated into a nonsignificant absolute difference in survival of 5.5% at 3 years with survival rates of 50% for those who did not receive chemotherapy compared to 55.5% for those who did. The results of this trial were updated in 2011, with a median patient follow-up of 8 years (Hall, 2002). The updated survival results were notable for a statistically significant 16% reduction in the risk of death for patients in the chemotherapy arm (HR = 0.84, 95% CI 0.72 to 0.99; $P = .37$). The estimated 10-year survival in the chemotherapy arm was 36% compared to 30% in the control arm, translating to a 6% absolute survival benefit (Griffiths et al, 2011). Limitations of the

EORTC/MRC trial when compared to current clinical practice include the fact that cisplatin, methotrexate, and vinblastine is not considered a standard of care for muscle-invasive bladder cancer and has not been compared directly to methotrexate, vinblastine, doxorubicin (Adriamycin), and cisplatin (MVAC). Additionally, approximately 40% of patients in both the chemotherapy arm and local therapy arm received radiation and not radical cystectomy.

The intergroup trial (Southwest Oncology Group [SWOG] 8710) randomized 317 patients to 3 cycles of neoadjuvant MVAC versus cystectomy alone for CT2-T4aN0M0 bladder cancer (Grossman et al, 2003a). Eighty-two percent of patients randomized to chemotherapy ultimately underwent a cystectomy with a mean time to surgery of 115 days. Thirty-eight percent of the chemotherapy patients achieved pT0 status at the time of cystectomy compared to 15% of the controls ($P < .001$). The median overall survival time in the chemotherapy group was 77 months compared to 46 months in the cystectomy-only group. The 5-year overall survival rates were 57% and 43% in the chemotherapy and cystectomy-only arms, respectively. However, the survival results failed to reach statistical significance ($P = .06$). Notably, patients who were downstaged to pT0 achieved excellent outcomes with 80% alive at 5 years compared to 40% of patients with residual disease. A secondary analysis of the SWOG 8710 data compared subgroup outcomes for patients with pure urothelial carcinoma versus mixed histologic subtypes (Scosyrev et al, 2011). The authors reported a survival advantage in the mixed histology subgroup that received neoadjuvant chemotherapy. Given the fact that this was a secondary subgroup analysis, it is difficult to draw definitive conclusions; however, this analysis does suggest that patients with mixed histology should be considered for neoadjuvant chemotherapy. Other randomized trials of neoadjuvant chemotherapy for bladder cancer are summarized in Table 94-4.

Most of the trials reported in the literature have failed to demonstrate a statistically significant survival advantage for those patients who received neoadjuvant chemotherapy. Contributing to these findings are inherent limitations to the trial designs including small sample sizes, varying and sometimes suboptimal chemotherapy protocols, premature closure, and inadequate follow-up (Sylvester and Sternberg, 2000). In an attempt to clarify further the precise benefit of neoadjuvant chemotherapy, several investigators have performed meta-analyses of the current chemotherapy trials. The Advanced Bladder Cancer (ABC) Meta-analysis Collaboration (2005a, 2005b) undertook the largest meta-analysis. This report was an update to the group's previous meta-analysis in 2003, now including the SWOG 8710 trial data for a total of 11 randomized neoadjuvant chemotherapy trials. Individual patient data were analyzed from 3005 patients making up 98% of patients from all known eligible trials. The trials were grouped based on the use of single agent platinum or platinum-based combination chemotherapy. There was a significant benefit in favor of platinum-based combination chemotherapy with regard to overall survival (HR = 0.86, 95% CI 0.77 to 0.95, $P = .003$). This resulted in an absolute survival benefit of 5%, improving overall survival from 45% to 50% at 5 years. Disease-free survival data were available on 2846 patients from 10 trials. There was a significant benefit in the platinum-based combination chemotherapy group (HR = 0.78, 95% CI 0.71 to 0.86, $P < .0001$). The 5% survival benefit was consistent across patient subgroups including age, sex, clinical stage, and performance status.

The Cancer Care Ontario Program in Evidence-based Care Practice Guidelines Initiative also reported a neoadjuvant chemotherapy meta-analysis (Winkvist et al, 2004). The authors reviewed 16 randomized-controlled trials (3315 patients) and identified 11 (2605 patients) with suitable data. The pooled HR was 0.90 (95% CI 0.78 to 0.96, $P = .02$) in favor of neoadjuvant chemotherapy. When the eight trials using cisplatin-based combination chemotherapy were analyzed, the pooled HR was 0.87 (95% CI 0.78 to 0.96, $P = .006$), consistent with an overall survival benefit of 6.5% (95% CI 2 to 11).

Based on the randomized trial results and subsequent meta-analyses, cisplatin-based neoadjuvant chemotherapy is associated with an overall survival advantage of 5% to 6% and a pathologic

TABLE 94-4 Randomized Trials of Neoadjuvant Chemotherapy

STUDY	NO. OF PATIENTS	NEOADJUVANT ARM	CONTROL ARM	STAGE	SURVIVAL RATE
EORTC/MRC (<i>International Collaboration of Trialists, 1999</i>)	976	CMV + RC/RT	RC/RT	T2-4aNxM0	10-yr OS: 36% vs. 30% ($P = .037$)

complete response rate of 30% to 40%. Currently the NCCN guidelines recommend clinicians strongly consider neoadjuvant cisplatin-based chemotherapy for cT2N0M0 patients and recommends neoadjuvant cisplatin-based chemotherapy for cT3-T4aN0M0 patients. The European Association of Urology guidelines currently recommend neoadjuvant chemotherapy for T2-T4aN0M0 patients and also note that it should always be a cisplatin-based combination regimen. Despite the evidence supporting neoadjuvant chemotherapy, it continues to be underused. An analysis of 7161 patients with stage III bladder cancer within the National Bladder Cancer Database noted that only 11.6% of patients received perioperative chemotherapy, of which 1.2% were in the neoadjuvant setting (*David et al, 2007*). SEER-Medicare data have also demonstrated a lack of penetrance of neoadjuvant chemotherapy in the setting of muscle-invasive disease (*Porter et al, 2011*).

ADJUVANT CHEMOTHERAPY FOR MUSCLE-INVASIVE BLADDER CANCER

Patients with pT3-T4 or node-positive disease are known to be at high risk for failure following cystectomy. Adjuvant chemotherapy has been used in this population in an attempt to treat micrometastatic disease and to improve survival. The rationale for systemic chemotherapy following cystectomy includes the fact that it allows for immediate local treatment with cystectomy and avoids any delay in treatment in patients with chemotherapy-resistant tumors (*Sternberg and Sylvester, 2014*). The availability of final pathology also allows clinicians to select patients at the highest risk for failure who are most likely to benefit, while sparing those who are less likely to progress from the side effects of systemic chemotherapy. Additionally, the role of molecular markers to predict disease aggressiveness and therapeutic response is likely to expand in the future. Cystectomy in this case would provide adequate tissue to direct individualized therapy based on molecular and genomic analysis.

A major limitation of adjuvant chemotherapy is that it is often difficult or impossible for patients to undergo systemic

therapy following cystectomy secondary to surgical deconditioning, deteriorating renal function, or perioperative complications (*Hall et al, 1996; Donat et al, 2009*). For example, in a randomized trial evaluating adjuvant chemotherapy for pT3-4/N+ disease, 25% of patients randomized to the chemotherapy arm did not receive such therapy (*Skinner et al, 1991*). Adjuvant chemotherapy trials have been hampered by small overall numbers and difficult patient accrual, which has limited the ability to draw definitive conclusions regarding the overall effectiveness of this approach.

Randomized Trials of Adjuvant Chemotherapy

There have been multiple randomized trials set forth to define the role of adjuvant chemotherapy (*Table 94-5*). Unfortunately these trials have not provided sufficient evidence to support adjuvant chemotherapy, and this is because of low numbers, difficulty with patient accrual, early termination of the trials, and flawed statistical design. The first prospective, randomized trial to demonstrate a survival benefit with adjuvant chemotherapy was reported by the University of Southern California (USC) group (*Skinner et al, 1991*). A total of 91 patients with pT3/T4 or N+ disease following cystectomy were randomized to cisplatin-based chemotherapy versus observation. Three-year time to progression was significantly better in the chemotherapy group with 70% of patients free of disease compared to 46% assigned to observation. Median survival was also significantly improved in the chemotherapy arm (4.3 years vs. 2.4 years; $P = .0062$). Although this trial did demonstrate an advantage in favor of adjuvant chemotherapy, it has been criticized for several reasons. First, the overall number of patients is small, which limits statistical power. Additionally, chemotherapy regimens were not standardized and included cisplatin, cyclophosphamide, and doxorubicin (Adriamycin) (CISCA)-like regimen, single-agent cisplatin, and chemotherapy regimens selected by clonal assays. This trial also highlighted the difficulty of administering chemotherapy after cystectomy with 25% of patients who were assigned to receive chemotherapy and who were not receiving therapy.

TABLE 94-5 Adjuvant Chemotherapy Trials Following Cystectomy

INVESTIGATOR	NO. OF PATIENTS	REGIMEN	CHEMO	NO CHEMO	RESULTS/SHORTCOMINGS
Logothetis et al, 1988	133	CISCA	62	71	Benefit; not randomized
Skinner et al, 1991	91	CAP	47	44	Benefit DFS 4.3 vs. 2.4 yr; few patients received therapy
Stockle et al, 1992, 1995	49	MVAC/MVEC	23	26	Benefit DSS (71.8 vs. 20.4 mo); no chemotherapy at relapse in control arm
Studer et al, 1994	77	DDP	40	37	No benefit
Bono et al, 1997	83	CM	48	35	No benefit for N0
Freiha et al, 1996	50	CMV	25	25	Benefit TTP (37 vs. 12 mo); early closure, no overall survival benefit
Otto et al, 2001	108	MVEC	55	53	No benefit
Cognetti et al, 2012	194	GC	102	92	No benefit for N0 or N+

CAP, cisplatin, cyclophosphamide, and doxorubicin; CISCA, cisplatin, cyclophosphamide, and doxorubicin (Adriamycin); CM, cisplatin and methotrexate; CMV, cisplatin, methotrexate, and vinblastine; DDP, diamminedichloroplatinum (cisplatin); GC, gemcitabine and cisplatin; MVAC, methotrexate, vinblastine, doxorubicin (Adriamycin), and cisplatin; MVEC, methotrexate, vinblastine, epirubicin, and cisplatin; TTP, time to progression.

A German trial randomized 49 patients with pT3b/T4a and/or N+ disease to receive 3 cycles of MVAC or MVEC (methotrexate, vinblastine, epirubicin, and cisplatin) (Stockle et al, 1992, 1995). A total of 26 patients were randomized to chemotherapy, and 69% received it. Three-year disease-free survival was significantly improved in the chemotherapy arm (63% vs. 13%, $P = .002$), and based on these results the study stopped early. This study was updated with a total of 83 patients (38 received chemotherapy after the close of the trial based on the interim analysis). Ten-year follow-up data maintained an advantage in the chemotherapy group with regard to progression-free survival (44% vs. 13%, $P = .02$) and disease-specific survival (42% vs. 17%, $P = .007$). Although there was a trend toward an overall survival benefit in the adjuvant chemotherapy arm, this was not statistically significant (27% vs. 17%, $P = .07$). Ultimately, 92% of patients in the observation arm showed evidence of tumor progression compared to 27% who received chemotherapy. Much like the USC trial, this trial has also been widely criticized. Overall, the number of patients is small because of early closure of the trial after interim analysis. Many patients in the observation group were not offered chemotherapy at the time of disease progression and, as one would expect, not all patients randomized to chemotherapy ultimately received such therapy.

Since the mid-2000s there have been several attempts at large-scale adjuvant chemotherapy trials, most of which have been presented in abstract form. Unfortunately, the majority of these studies have been hampered by poor accrual. The results of an Italian adjuvant chemotherapy, multicenter, randomized phase III trial have been published (Cognetti et al, 2012). This study randomized 194 patients with pT2G3, pT3-4, N0-2 urothelial carcinoma to observation ($n = 92$) versus four cycles of chemotherapy ($n = 102$). The chemotherapy cohort was randomly assigned to one of two regimens; either gemcitabine 1000 mg/m² days 1, 8, and 15 and cisplatin 70 mg/m² day 2 or the same gemcitabine schedule plus cisplatin 70 mg/m² day 15, every 28 days. With a median follow-up of 35 months, the 5-year overall survival was 48.5% with no difference between the chemotherapy and observation arm ($P = .24$). There was also no statistical difference in disease-free survival in the observation (42.3%) and chemotherapy arms (37.2%). Only 62% of patients received the planned course of chemotherapy, however. The initial study was designed to randomize 610 patients in a 1:1 fashion, but was closed early because of poor accrual. The smaller sample size resulted in significant underpowering of the study in detecting a significant difference between adjuvant chemotherapy and observation.

The Cancer and Leukemia Group B (CALGB) trial randomized patients following cystectomy with acceptable renal function to either a rapid cycling regimen of chemotherapy with 4 cycles of

doxorubicin-gemcitabine administered at 14-day intervals with granulocyte colony-stimulating factor (G-CSF) support followed by 4 cycles of paclitaxel-cisplatin provided at 21-day intervals compared to adjuvant gemcitabine with cisplatin in a 4-week cycle (Bajorin, 2001). The accrual goal in this trial was 800 patients; however, the study was terminated for poor accrual, and ultimately fewer than 100 patients enrolled. Similarly, the EORTC-30994 trial randomized patients with pT3-4 and/or N+ disease with acceptable renal function to either 4 cycles of either gemcitabine/cisplatin, MVAC, or High Dose Intensity (HD) MVAC versus observation. The accrual goal for this trial was 660 patients, but it closed as a result of poor accrual enrolling a total of 278 patients (Sternberg et al, 2001c). The USC/SWOG International trial randomized 114 patients with pT1-2, N0, p53-positive tumors to 3 cycles of adjuvant MVAC or observation (Stadler et al, 2009). A total of 114 patients were randomized, but further accrual was halted after interim analysis showed no difference in recurrence-free survival. Additionally, 67% of those randomized to MVAC received all 3 cycles and 12% received none. The Spanish Oncology Genitourinary Group (SOGUG) 99/01 trial randomized patients with pT3-4 or node-positive disease to 4 cycles of paclitaxel, gemcitabine, and cisplatin versus observation. At a median follow-up of 51 months, a 5-year overall survival advantage was noted with chemotherapy (60% vs. 31%, $P < .0009$); however, the trial was stopped prematurely because of poor accrual after 7 years after randomizing 142 patients, which was well below the target of 340.

Similar to the neoadjuvant chemotherapy, the Advanced Bladder Cancer (ABC) Meta-analysis Collaboration (2005a, 2005b) evaluated the effect of adjuvant chemotherapy reviewing 11 randomized trials and ultimately including 6 trials with a total of 491 patients. The overall HR for survival from this meta-analysis was 0.75 (95% CI 0.60 to 0.96, $P = .019$) suggesting a 25% relative reduction in the risk of death in favor of adjuvant chemotherapy compared to controls. This translated to a 9% absolute survival benefit at 3 years. Despite the positive findings, the authors of the meta-analysis point out that insufficient evidence remains to base treatment decisions reliably. Notably, there were major deficiencies in the trials included in the meta-analysis such as small sample sizes, early closure of trials, limitations in statistical analysis, and differences in the way disease-free survival was defined (Sternberg and Collette, 2006a).

Despite the efforts of the trials outlined previously, the evidence for adjuvant chemotherapy is lacking. An updated meta-analysis including 945 patients noted that adjuvant chemotherapy seems to be most beneficial to patients with node-positive disease; however, this meta-analysis was limited by many of the same issues outlined earlier (Leow et al, 2014). The available evidence suggests perioperative chemotherapy does confer a survival benefit for bladder

cancer patients, with stronger evidence available in the neoadjuvant approach. The optimal approach and benefit to systemic chemotherapy in the adjuvant setting remains incompletely defined, and based on the difficulty with patient accrual in past trials it may remain unanswered. Currently the NCCN guidelines favor neoadjuvant chemotherapy instead of adjuvant chemotherapy based on higher-level evidence data; however, the guidelines do suggest considering adjuvant chemotherapy in the setting of pT3-4 or node-positive disease based on the available data. The EUA guidelines currently recommend adjuvant chemotherapy within clinical trials but not as a routine therapeutic option, as randomized trials and meta-analyses have not provided sufficient evidence to support routine use.

BLADDER PRESERVATION

Although radical cystectomy remains the standard of care for patients with muscle-invasive bladder cancer, it is a major operative procedure with significant risk of perioperative morbidity and mortality (Shabsigh et al, 2009). Data from Medicare claims have shown radical cystectomy to have the second highest 30-day readmission rate compared to other urologic and nonurologic procedures (Goodney et al, 2003). The high incidence of perioperative complications, coupled with a classically older patient population with multiple medical comorbidities, has led patients and clinicians to seek alternatives to cystectomy. Bladder preservation should be undertaken with the goal of curative therapy and to maintain a functionally intact bladder.

Historical series have demonstrated inferior results with single modality therapy (radical TUR, chemotherapy alone, or radiation alone) compared to that of radical cystectomy. With this in mind, successful bladder preservation should be viewed as a multimodal therapy involving aggressive TUR, systemic chemotherapy, and radiation therapy. Appropriate patient selection is also extremely important to optimize response to bladder-sparing protocols. Each patient should be thoroughly evaluated regarding perioperative risk before undergoing radical cystectomy. Patients who are medically unfit for surgery or who refuse surgery can be considered for bladder preservation. Patients who are deemed “medically fit” to undergo cystectomy should be offered cystectomy as the standard of care; however, bladder preservation is a reasonable option for those who are highly selected and counseled appropriately. Patients with hydronephrosis, obvious T3 disease on imaging, presence of CIS, multifocal tumors, and/or incomplete macroscopic tumor resection are suboptimal candidates for bladder preservation.

Single Modality Treatment

Radical Transurethral Resection

Primary support for radical TUR as a single modality therapy for patients with T2 disease is largely based on the finding of p0 disease in approximately 10% of patients treated with radical cystectomy alone. A major limitation of radical TUR monotherapy is the significant risk of occult extravesical disease noted in patients with clinical T2 disease. Pathologic T3 and pT4 disease has been noted in cT2 cystectomy specimens in up to 40% and 9% of patients, respectively (Karakiewicz et al, 2006b). Additionally, multiple radical cystectomy series have consistently shown an approximately 25% risk of occult nodal metastasis at the time of surgery (Stein et al, 2001). Therefore, TUR monotherapy in upwards of 50% of patients presenting with muscle-invasive bladder cancer would be undertreatment. In highly selected patients, however, several authors have reported reasonable long-term results with this approach.

In a series of 133 patients and a minimum of 15-year follow-up, radical TUR was reported to have a disease-specific survival of 82%, 80%, and 77% and progression-free survival of 76%, 65%, and 58% at 5, 10, and 15 years, respectively (Solsona et al, 2010). Patients were excluded from this approach if they presented with tumors greater than 3 cm or hydronephrosis. Patients with CIS at the time

of TUR were treated with intravesical therapy. Wide resection of the TUR site was also performed at 3 and 6 months, and the patients underwent intensive endoscopic surveillance every 3 months for 2 years, every 6 months for 3 years, and annually thereafter. Long-term results with TUR monotherapy (≥ 10 years) have also been reported by the MSKCC group (Herr, 2001). This cohort of 99 patients with muscle-invasive disease all underwent a restaging TUR that demonstrated either no tumor (74%) or residual non-muscle-invasive disease (26%) before enrolling in a bladder-preservation protocol. The 5- and 10-year disease-specific survival rates were 82% and 76% with actual bladder preservation rates of 67% and 57%, respectively. Patients with cT0 disease at the time of restaging TUR achieved the best long-term responses with a 10-year disease-specific survival of 82% compared to 57% for those with residual non-muscle-invasive disease. A third of the patients ultimately developed muscle-invasive bladder cancer, of which nearly half (47%) died of disease. The MD Anderson group has also reported on a smaller cohort of patients treated with TUR monotherapy and a median follow-up of 2.5 years (Leibovici et al, 2007). Criteria for TUR monotherapy in this cohort included no residual tumor at the resection site on repeat TUR, normal examination under anesthesia, normal upper urinary tract evaluation, and no urethral involvement. Of the 327 patients who presented with muscle-invasive bladder cancer during a 6-year period, 35 (11%) met entry criteria and 27 elected for bladder preservation. With a median follow-up of 2.5 years, 44% remained free of disease, whereas 56% experienced a recurrence. Of the 15 patients who had a subsequent recurrence, one presented with lymph node positive disease. Eight patients ultimately underwent cystectomy, of which five showed extravesical disease on final pathology.

Although specifically selected individuals can achieve a durable response with radical TUR, most patients presenting with muscle-invasive bladder cancer are not appropriate candidates and will not be cured with TUR monotherapy. If a patient is going to elect TUR monotherapy, that patient should be properly informed regarding risk of recurrent disease and should be appropriately selected based on clinical criteria including a negative restaging TUR, no hydronephrosis, no evidence of adenopathy, tumor size less than 3 cm, and lack of multifocal disease.

Partial Cystectomy

Compared to radical TUR, partial cystectomy offers two distinct advantages. First, a full pelvic lymphadenectomy can be performed that allows for complete staging. Second, the full thickness of bladder wall and associated perivesical fat can be removed. Historically, partial cystectomy was associated with poor outcomes including 5-year overall survival rates as low as 24% (Kassouf et al, 2006) and high rates of local recurrence and wound recurrences. However, with more stringent selection criteria, partial cystectomy can be associated with acceptable oncologic outcomes.

Ideal candidates for partial cystectomy include those with small, solitary tumors amenable to wide resection with 2-cm margins. Ideally the tumor should be away from the ureteral orifices to avoid reimplantation. It is imperative that the tumor is in a location that allows for complete resection while maintaining adequate functional bladder capacity. Partial cystectomy is also the treatment of choice for urachal adenocarcinoma; however, these lesions are distinct pathologic entities from urothelial carcinoma and the studies that follow are specific to urothelial carcinoma. The presence of CIS is considered by most to be a contraindication to partial cystectomy, and random bladder biopsies can be performed preoperatively. The MSKCC group has also recommended the routine use of intraoperative frozen sections and proceeding with radical cystectomy if a negative margin cannot be achieved (Holzbeierlein et al, 2004). Using strict selection criteria, long-term oncologic results can approach that of radical cystectomy (Holzbeierlein et al, 2004; Kassouf et al, 2006).

Contemporary series demonstrate non-muscle-invasive recurrences in 12% to 50%, muscle-invasive recurrences in 17% to 57%, and metastatic recurrence in 14% to 52% of cases, respectively

(Holzbeierlein et al, 2004; Kassouf et al, 2006; Smaldone et al, 2008). The 5-year overall, recurrence-free and disease-specific survival in the same series were 67% to 70%, 39% to 62%, and 84% to 87%, respectively. Bladder intact rates and bladder intact without evidence of disease rates were reported by the MSKCC and the MD Anderson groups as 65% to 74% and 49% to 67%, respectively. Salvage cystectomy may be necessary in up to a quarter of patients and can be associated with a cure in 75% of cases. It is important to note the presence of late recurrence of muscle-invasive disease in 3 patients (41, 44, and 138 months) in the MD Anderson experience, highlighting the need for long-term follow-up in such patients. There are risk factors for recurrence after partial cystectomy.

Partial cystectomy has also been reported in combination with neoadjuvant chemoradiation therapy. Koga and colleagues have reported on 46 patients with muscle-invasive bladder cancer who were treated with this approach (Koga et al, 2012). Selection criteria included a solitary tumor comprising less than 25% of the total bladder area, no involvement of the bladder neck or trigone, and a complete TUR. Treatment consisted of 40 Gy of external beam radiation concurrently with two cycles of cisplatin (20 mg/day for 5 days). Only 3 patients (7%) showed residual muscle-invasive disease at the time of partial cystectomy. At a median follow-up of 45 months, the 5-year overall and cancer-specific survival were both 100%. Whereas radical cystectomy remains the gold-standard therapy following neoadjuvant chemotherapy, resection of the primary tumor site with partial cystectomy has been used in partial and complete responders (Herr et al, 1998; Sternberg et al, 2003). Adjuvant chemotherapy has been reported to improve progression-free survival in patients with adverse pathologic features at the time of partial cystectomy (Kassouf et al, 2006); however, absolute numbers are small, warranting further studies to define the role of adjuvant therapy partial cystectomy.

Radiation Monotherapy

Radiation therapy has been used to treat muscle-invasive bladder cancer since before the mid-1980s. For clarity of presentation in this section, the term radiation monotherapy will also be used to describe studies in which debulking TUR was performed before radiation. The rationale for this terminology is that it is often difficult to ascertain exactly how complete the debulking TUR was that was performed across various series, which likely varies from institution to institution. Radiation therapy is typically administered in a 1.5- to 2.0-Gy dose per fractions, although higher doses have been reported in Europe. Total dose is generally between 55 and 65 Gy. Higher doses have been shown to improve local response rates, but these come at the cost of increased toxicity.

Five-year overall survival rates have been reported from 26% to 50%; however, local failures can be seen in more than 30% of cases when radiation is used as monotherapy. Rodel and colleagues (2002) reported on 126 patients treated with radiation monotherapy. The authors reported 5- and 10-year overall survival rates of 40% and 19%, respectively, which were inferior to results obtained with a chemoradiation regimen. As with cystectomy series, response to radiation monotherapy is largely dependent on the stage of disease. Local control rates have been reported to be as low as 27% for patients with T3 disease (Pollack et al, 1996). A more recent multicenter study demonstrated more favorable results for radiation monotherapy (2-year disease-free survival of 54% and 5-year overall survival of 35%); however, improved survival was noted in patients treated with combined chemoradiation therapy (James et al, 2012). Prognostic factors for local failure after radiation monotherapy are similar to those of radical TUR, including tumor multifocality, presence of hydronephrosis, and higher clinical T stage.

Combined external beam radiation and brachytherapy have also been explored as possible bladder preservation techniques. Using a technique of 30 Gy of external beam radiation followed by 40 Gy of brachytherapy, Nieuwenhuijzen and colleagues (2005) reported 5- and 10-year overall survival rates of 62% and 50%, with 5- and 10-year disease-specific survival rates of 73% and 67%, respectively. The local control rate at 5 years was 73%. Survival

results were similar to radical cystectomy patients at the same institution during that time period; however, this was not a prospective, randomized trial and therefore definitive conclusions compared to radical cystectomy outcomes are not valid. Additionally, patients with high-grade T1 bladder cancer were also included in this analysis, limiting its generalizability to a population of strictly muscle-invasive patients.

Radiation monotherapy currently should be considered inferior to that of combined chemoradiation therapy, but it can be considered in the palliative setting or for patients who are otherwise unfit and unwilling to undergo any other form of therapy (chemotherapy or surgery).

Primary Chemotherapy

The primary role for systemic chemotherapy in the treatment of muscle-invasive bladder cancer has been in the neoadjuvant or adjuvant setting in combination with radical cystectomy. Similar to radiation monotherapy, it is generally accepted that combination chemoradiation therapy is superior to chemotherapy alone. It is well established that an increased proportion of patients who receive neoadjuvant chemotherapy will have p0 disease at the time of cystectomy. Radical cystectomy remains the standard of care in patients who have had a complete response to neoadjuvant therapy; however, patients have refused cystectomy in this setting. The MSKCC group has reported outcomes for 63 patients who declined cystectomy after achieving a complete response with neoadjuvant chemotherapy (Herr, 2008). At a minimum of 5 years of follow-up, 64% of patients were alive and 54% exhibited an intact bladder. Thirty-six percent of the cohort ultimately died of bladder cancer, of which the majority relapsed with invasive disease in the bladder. Predictors of prolonged survival with chemotherapy alone in this group included small solitary tumors and low-stage, completely resected tumors. Sternberg and colleagues have also reported on the use of systemic MVAC and TUR with the intention of bladder preservation (Sternberg et al, 2003) in 104 patients. Following completion of chemotherapy, patients underwent a repeat TUR and 49% were noted to have a complete response. Sixty percent of patients were alive at a median follow-up of 56 months without further therapy. Patients downstaged to pT0 or to non-muscle-invasive disease exhibited superior survivals compared to those with persistent muscle-invasive disease. These data suggest that some patients with low-risk muscle-invasive tumors can be cured with TUR and chemotherapy alone. However, the results presented earlier were obtained at specialized centers and it is unknown whether they can be applied to other practice settings.

Trimodal Therapy

Although radical cystectomy with neoadjuvant chemotherapy remains the gold standard by which all other treatments for muscle-invasive bladder cancer should be measured, several studies have shown bladder preservation to be a reasonable option in highly selected patients. Ideal candidates for bladder preservation should have good baseline bladder function, have a complete resection of all visible tumors endoscopically, have small solitary tumors with limited CIS, and have no evidence of hydronephrosis. If held to strict criteria, approximately 6% to 19% of patients presenting with muscle-invasive bladder cancer could be considered as candidates for such an approach (Smith et al, 2013). The major chemoradiation bladder preservation trials are summarized in Table 94-6.

Two basic strategies for trimodal bladder preservation exist: split-course and continuous-course therapy. Split-course therapy is based on the premise of midtreatment restaging. Patients are administered induction chemoradiation therapy to approximately 40 Gy, which is followed by restaging with cross-sectional imaging and endoscopic evaluation. If persistent invasive disease is noted, radical cystectomy is recommended. Those without persistent invasive disease undergo consolidative chemoradiotherapy to approximately 64 Gy. As the name implies, continuous-course treatment involves a full course of chemoradiation therapy followed by an endoscopic

TABLE 94-6 Major Prospective Trimodal Bladder Preservation Studies

STUDY	NO. OF PATIENTS	STAGE	CHEMOTHERAPY	RT	CR RATE	SALVAGE CYSTECTOMY RATE	SURVIVAL
Housset et al, 1993	54	T2-4N0-1Mx	Cisplatin + 5-FU × 4	44 Gy	74%	NA	3-yr CSS 62%, OS 59%
Shipley et al, 1998	62	T2-4aN0Mx	Cisplatin × 3	64.8 Gy	60%	25.8%	5-yr OS 49%
Tunio et al, 2012	200	T2-4N0Mx	Cisplatin weekly	65 Gy	93%		5-yr OS 52%
James et al, 2012	182	T2-4aN0Mx	5-FU, MMC × 2	55 or 64 Gy		11.4%	5-yr OS 48%

Kaufman et al, 2009a, 2009b	50	T2-4aN0Mx	Weekly cisplatin + paclitaxel	64.3 Gy	87%		5-yr OS 56%, 5-yr CSS 71%

CR, complete response; CSS, cause-specific survival; 5-FU, 5-fluorouracil; MMC, mitomycin C; OS, overall survival.

restaging examination 6 months after therapy to allow time for an adequate response to therapy. Regardless of approach, maximal tumor debulking before trimodal therapy is critical to optimize therapeutic results. Studies have demonstrated improved 5- and 10-year overall survival rates for patients with complete TURs (57% and 39%) compared to those without complete resection (43% and 29%) before trimodal therapy. Additionally, the rates of radical cystectomy for visibly complete resections are lower (11%) compared to incomplete resections (42%) (Efsthathiou et al, 2012).

The split-course approach has largely been developed within the Radiation Therapy Oncology Group (RTOG). The RTOG has completed six prospective protocols using slightly different techniques to evaluate the efficacy of trimodal therapy for muscle-invasive disease. In total, 415 patients were entered into these trials. The 5-year overall survival rate was approximately 50% for the entire cohort with 75% of patients achieving a “cure” while maintaining an intact bladder (Shipley et al, 2003). The most recent RTOG protocol randomized 93 patients with cT2-T4, N0 disease to cisplatin/paclitaxel or cisplatin/5-fluorouracil (5-FU) with induction and consolidation radiotherapy followed by adjuvant gemcitabine/paclitaxel/cisplatin. Induction dose radiotherapy was 40.3 Gy, with a consolidation dose of 24 Gy. If T1 or higher disease was found after induction therapy, salvage radical cystectomy with adjuvant chemotherapy was performed. With a median follow-up of 3 years, the complete response rate was 72% and 62% for cisplatin/paclitaxel and cisplatin/5-FU, respectively. The bladder-intact survival rates at 4 years were 73% and 69%, respectively. Late grade toxicity greater than or equal to 3 was noted in 9% and 4% of patients, respectively. The Massachusetts General Hospital has reported the largest institutional experience with split-course trimodal therapy. They have published long-term results regarding their 348-patient cohort with 5-, 10-, and 15-year overall survival rates of 52%, 35%, and 22%, respectively. As expected, the overall survival rates are best for those with cT2 disease at 61%, 43%, and 28% compared to 41%, 27%, and 16% for those with T3/T4 tumors. The 5-, 10-, and 15-year disease-specific survival rates were 64%, 59%, and 57%, respectively, with bladder-intact rates of 60%, 45%, and 36%, respectively (Efsthathiou et al, 2012).

Continuous-course trimodal therapy has also been reported in long-term institutional series as well as prospective trials. A multicenter, phase 3 trial randomized 360 patients to continuous-course chemoradiation therapy compared to radiation therapy alone. Patients in the chemoradiation cohort received mitomycin followed by 5-FU in conjunction with radiation. The primary end point was locoregional disease-free survival. The secondary end points were overall survival and toxicity. At 2 years, the locoregional disease-free survival in the chemoradiation therapy group was 67%. The 5-year overall survival rate was 48%, and there was no significant increase in toxicity compared to the radiation-only group (James et al,

2012). Another large series of continuous-course chemoradiation therapy has been reported in Germany, in which the majority of patients received cisplatin-based chemotherapy. In this series of 331 patients, the 5-, 10-, and 15-year overall survival rates were 54%, 36%, and 24%, respectively. Stratifying patients by T2/T3 disease yielded overall survival rates of 45%, 26%, and 16%; whereas patients with T4 disease fared far worse. The overall 5-year bladder-intact survival was 40% to 54% (Rodel et al, 2002; Krause et al, 2011).

Direct comparisons between bladder preservation and radical cystectomy series cannot be made. Prospective trials are needed to compare the efficacy of trimodal therapy to that of radical cystectomy; however, it is worth noting that reported outcomes from trimodal therapy series are comparable to those of surgical series. Following trimodal therapy, although there is no universally accepted follow-up regimen, close surveillance with cross-sectional imaging and cystoscopy are necessary.

PROGNOSTIC NOMOGRAMS FOR MUSCLE-INVASIVE BLADDER CANCER

As detailed in previous sections, the TNM staging system provides valuable prognostic information following radical cystectomy. Despite its usefulness, there is often wide variation between patients with regard to absolute risk of recurrence as a result of the heterogeneity of tumor biology and patient characteristics. Better understanding and prediction of disease outcome is important to deliver appropriately the adjuvant therapy and to counsel patients with regard to the risk of disease recurrence. The use of standard pathologic data to predict outcomes was discussed in previous sections. Nomograms have been developed in an effort to predict better the prognosis in patients with muscle-invasive disease (Bochner et al, 2006; Karakiewicz et al, 2006a; Shariat et al, 2006a). In addition to standard pathologic features, molecular markers are now being incorporated into predictive models not only to improve prognostic accuracy, but also to provide the potential to predict response to therapy (Karam et al, 2007; Shariat et al, 2008; Youssef et al, 2009; Shariat et al, 2010).

Nomograms incorporating clinical, pathologic, and molecular data have been developed as predictive tools in the muscle-invasive setting (Fig. 94-2). Two consortia have published easy-to-use nomograms for predicting recurrence following radical cystectomy. The International Bladder Cancer Consortium (IBCC) collected data on 9064 patients from 12 centers of excellence (Bochner et al, 2006). Significant variables in the nomogram included age, grade, pathologic stage, histologic subtype, lymph node metastasis, and timing of surgery. The final nomogram was significantly superior to standard prediction models in predicting disease-free survival following

Figure 94-2. To obtain nomogram-predicted probability of recurrence, locate patient values at each axis. Draw a vertical line to the “Point” axis to determine how many points are attributed for each variable value. Sum the points for all variables. Locate the sum on the “Total Points” line. Draw a vertical line toward the 2YrRecFP, 5YrRecFP, and 8YrRecFP axes to respectively determine the 2-year recurrence-free probability, 5-year recurrence-free probability, and 8-year recurrence-free probability. RFS, recurrence-free survival. **A**, Postoperative nomogram for predicting recurrence after radical cystectomy. **B**, Postoperative nomogram for predicting recurrence after radical cystectomy incorporating tissue biomarkers. CIS, carcinoma in situ; LVI, lymphovascular invasion. (A, From Karakiewicz PI, Shariat SF, Palapattu GS, et al. Nomogram for predicting disease recurrence after radical cystectomy for transitional cell carcinoma of the bladder. *J Urol* 2006;176(4):1354–62; B, from Shariat SF, Karakiewicz PI, Ashfaq R, et al. Multiple biomarkers improve prediction of bladder cancer recurrence and mortality in patients undergoing cystectomy. *Cancer* 2008;112(2):315–25.)

cystectomy (CI 0.75) compared to TNM stage (CI 0.68) or standard pathologic grouping models (CI 0.62). The authors modeled several lymph node variables including total number removed, number of positive nodes, and lymph node density, but found binary node status (positive vs. negative) to be the best predictor. The Bladder Cancer Research Consortium (BCRC) has also published a postcystectomy nomogram based on 728 patients from 3 centers (Karakiewicz et al, 2006a). As opposed to the IBCC nomogram, all patients in the BCRC had urothelial histology. Multivariate predictors of disease recurrence, cancer-specific mortality, and all-cause mortality at 2, 5, and 8 years postcystectomy included pT stage, nodal status, lymphovascular invasion, perioperative chemotherapy administration, and adjuvant radiation therapy. The nomogram improved predictive accuracy in favor of that of the AJCC staging system by 3.2% (0.748 vs. 0.780). Both nomograms have been validated in other patient cohorts (Zaak et al, 2010).

Although postcystectomy nomograms provided enhanced prognostic value following treatment, precystectomy nomograms may include a greater impact in directing definitive therapy including neoadjuvant chemotherapy decisions. Using the same multicenter cystectomy cohort, Karakiewicz and colleagues (2006b) evaluated 726 patients and developed a nomogram incorporating age, TUR stage, tumor grade, and the presence of CIS. The multivariate nomogram was 75.7% accurate versus TUR stage (71.4%) in predicting non-organ-confined disease (pT3 or 4). The nomogram was also more accurate (63.1% vs. 61%) in predicting lymph node metastasis on final pathology. Although the overall performance characteristics of this nomogram did not dramatically improve the ability to predict non-organ-confined disease, it does demonstrate the usefulness and future potential of multivariable nomograms in the predictive setting. A nomogram has also been published to predict response rates to trimodal bladder preservation therapy (Coen et al, 2013). A cohort of 325 patients who underwent bladder preservation at a single institution was used in this evaluation. The final nomogram incorporated clinical T stage, presence of hydronephrosis, completeness of TUR, age, gender, and tumor grade. The ROC (receiver operating characteristic) curve for a complete response to therapy using this nomogram was 0.69, and for bladder-intact disease-free survival it was 0.61.

Although nomograms appear to improve predictive accuracy over standard pathologic criteria, the addition of molecular markers has the potential to aid diagnostic accuracy further. Molecular markers are important in cell-cycle signaling and angiogenesis pathways, and their expression can be quantified by immunohistochemical staining. Inclusion of single biomarkers into prognostic nomograms is unlikely to enhance significantly the prognostic capability owing to the complex tumor heterogeneity and biology. Shariat and associates (2008) studied the use of adding the molecular markers p53, pRB, p21, p27, and cyclin E1 into a nomogram. By adding the molecular markers, the nomogram improved predic-

tive accuracy for recurrence and cancer-specific survival by 10.9% and 8.6%, respectively, for patients with pTa-3N0M0 bladder cancer following radical cystectomy. Shariat and colleagues (2012) have also evaluated p53, p27, p21, and pRB in 272 cystectomy patients and in an external testing cohort of 52 patients with chemotherapy-naïve pT1-2N0M0 urothelial carcinoma. Overall, 80% of patients showed expression of at least one marker. The addition of the number of altered markers increased the accuracy of the base model for disease recurrence and cancer-specific mortality by 15.6% and 14.8%, respectively.

Nomograms, particularly those using novel molecular markers, have demonstrated improved predictive accuracy in favor of standard TNM factors alone. To date, these studies have been performed in retrospective cystectomy and bladder-sparing cohorts and require further validation in the prospective setting. Such nomograms provide the potential to aid clinicians in direct treatment both before definitive treatment (neoadjuvant chemotherapy vs. surgery) and after treatment (adjuvant therapy vs. surveillance).

MANAGEMENT OF METASTATIC BLADDER CANCER

Systemic cisplatin-based combination chemotherapy is the standard of care for patients with metastatic urothelial bladder cancer. First-line systemic regimens include MVAC, HD-MVAC, and gemcitabine/cisplatin (Sternberg et al, 1989; Loehrer et al, 1992; Saxman et al, 1997; von der Maase et al, 2005; Sternberg et al, 2006b). Although the majority of patients with metastatic disease (40% to 70%) will experience an initial response to chemotherapy, most will ultimately progress with a median survival of 14 months and overall 5-year survival rates of 5% to 20% (Table 94-7) (Saxman et al, 1997; von der Maase et al, 2005; Sternberg et al, 2006b; Bellmunt et al, 2012). Despite the initial effectiveness of systemic cisplatin-based chemotherapy, there are several barriers to optimal delivery of chemotherapy in the bladder cancer population. Renal insufficiency is not uncommon in this population, limiting the use of cisplatin. Additionally, poor performance status, medical comorbidity, and frailty are often preexisting conditions that can limit a patient's ability to tolerate systemic therapy. A working group of medical oncologists have published criteria to define patients who are not cisplatin candidates, including any of the following: a World Health Organization or Eastern Cooperative Oncology Group performance status greater than 2, creatinine clearance less than 60 mL/min, grade 2 or above audiometric hearing loss, grade 2 or above peripheral neuropathy, or a New York Heart Association Class III or higher heart failure (Galsky et al, 2011). When cisplatin therapy is contraindicated, carboplatin has been substituted with the benefit of improved tolerability but with the cost of decreased efficacy (Petrioli et al, 1996; Bellmunt et al, 1997; Dogliotti et al, 2007). Although carboplatin is a reasonable choice for patients in whom

cisplatin is contraindicated, it should not be considered a first-line therapy for those who are cisplatin candidates.

Poor performance status and the presence of visceral metastasis predict a poor response to chemotherapy for patients with locally advanced or metastatic urothelial carcinoma. The MSKCC group has published their data on 203 patients with unresectable or metastatic bladder cancer treated with MVAC (Bajorin et al, 1999). They found a Karnofsky performance status of less than 80% and visceral (lung, liver, bone) metastasis to be independent predictors of poor outcome. Median survival times for patients who had zero, one, or two risk factors were 33, 13.4, and 9.3 months, respectively.

Randomized Trials in Metastatic Bladder Cancer

A phase III Intergroup randomized trial examined the effectiveness of MVAC therapy to that of single-agent cisplatin in patients with metastatic or locally advanced bladder cancer (Loehrer et al, 1992). A total of 269 patients were randomized, and those patients in the MVAC arm were noted to have significantly higher response rates (39% vs. 12%) and overall survival rates (12.5 vs. 8.2 months). Although superior in efficacy, the MVAC arm was more toxic with regard to leukopenia, mucositis, granulocytopenic fever, and drug-related mortality (3% to 4%). MVAC has also been compared to CISCA in patients with advanced urothelial carcinoma (Logothetis et al, 1990). In this study, 110 patients (86 bladder, 23 upper tract, 1 prostatic urethra) were randomized, with the MVAC regimen demonstrating improved response rates (65% vs. 46%) and overall survival (11.2 vs. 8.4 weeks) compared to CISCA.

Although most patients with metastatic urothelial carcinoma experience some response (complete or partial) to MVAC, the long-term survival rates are dismal (Saxman et al, 1997; Bajorin et al, 1999). In an effort to improve these results, Sternberg and coworkers (2001b) investigated whether increasing the dose intensity of MVAC with G-CSF could improve complete response rates and survival. In this study, 263 patients with chemotherapy-naïve metastatic or advanced urothelial carcinoma were randomized to HD-MVAC (MVAC + G-CSF; 2-week cycle) versus standard MVAC (4-week cycle). The HD-MVAC arm did achieve higher complete response rates (21% vs. 9%) and improved progression-free survival (9.1 vs. 8.2 months); however overall survival was not significantly different between the two groups. Seven years later, additional follow-up was reported in this same cohort (Sternberg et al, 2006b). In the updated analysis, HD-MVAC was reported to have a statistically significant relative reduction in the risk of progression and death compared to that of MVAC (HR = 0.76; 95% CI 0.58 to 0.99; $P = .042$).

Although MVAC has demonstrated efficacy in treating urothelial carcinoma, it has significant toxicity. The toxicity of MVAC led to trials of alternative less-toxic chemotherapy regimens. Most notably, a phase III randomized trial comparing gemcitabine/cisplatin to MVAC was conducted in 405 patients (von der Maase et al, 2000,

2005). There was no difference in response rates (49% vs. 46%), time to progression (7.4 vs. 7.4 months), and overall survival rates (13.8 vs. 14.8 months) between the two study arms. The updated study analysis confirmed equivalence of the two regimens (HR: 1.09, 95% CI 0.88 to 1.34; $P = .66$). The gemcitabine/cisplatin regimen was better tolerated with only 37% of patients in that arm requiring dose modifications compared to 63% in the MVAC arm. Patients in the gemcitabine/cisplatin arm also experienced less grade 3/4 neutropenia, neutropenic fever, neutropenic sepsis, and mucositis. The toxicity-related death rate was also lower in the gemcitabine/cisplatin group (1% vs. 3%). Owing to its equivalent efficacy and better tolerability, gemcitabine/cisplatin is the most widely used chemotherapeutic regimen for muscle-invasive and metastatic bladder cancer.

Randomized trials have also assessed the usefulness of adding additional drugs to standard chemotherapy regimens (Bellmunt et al, 2000; von der Maase et al, 2006). The largest such trial was a phase III study that compared paclitaxel, gemcitabine, and cisplatin (PGC) to standard gemcitabine/cisplatin in 626 patients with locally advanced or metastatic urothelial cancer (Bellmunt et al, 2012). Overall response rates were significantly higher in the PGC arm (55.5% vs. 43.6%, $P = .0031$); however there was not a significant improvement in overall survival (15.8 vs. 12.7 months; HR = 0.85; 95% CI 0.72 to 1.02, $P = .075$). There was also significantly more grade 3 and 4 neutropenia and thrombocytopenia in the PGC arm. A summary of the major chemotherapy trials for metastatic bladder cancer is presented in Table 94-7.

Second-Line Chemotherapy

There is no clear standard second-line chemotherapy for patients who progress or do not respond to first-line therapy. Patients who fail first-line chemotherapy have a dismal prognosis. Salvage chemotherapy in this setting with conventional agents typically has a suboptimal response rate (Dreicer et al, 1996; McCaffrey et al, 1997; Lorusso et al, 1998; Albers et al, 2002; Vaughn et al, 2002) (Table 94-8).

Single-Agent Second-Line Chemotherapy

Multiple novel single agents have been evaluated in patients with advanced bladder cancer, typically with modest response rates of less than 20%.

Vinflunine is a novel antitubulin agent obtained from a vinca alkaloid (Culine, 2006). Bellmunt and coworkers (2009) compared vinflunine plus best supportive care (BSC) versus BSC alone in patients with metastatic urothelial carcinoma previously treated with first-line platinum chemotherapy. Overall, 370 patients were randomized with a 9% response rate in the vinflunine arm. At the time of initial publication, the results of the study met the 2.3-month improvement in overall survival (6.9 vs. 4.6 months),

N, number of patients; OS, overall survival; PFS, progression-free survival; RR, response rate.

however this did not achieve statistical significance. The authors published updated survival results in 2013, at which time overall survival had reached statistical significance in favor of the vinflunine arm (HR = 0.719; 95% CI 0.570 to 0.906, $P = .0052$) (Bellmunt et al, 2013). Vinflunine is currently approved in Europe as a second-line agent for metastatic bladder cancer. A phase III clinical trial (NCT00389155) is currently underway in cisplatin-ineligible patients with advanced urothelial carcinoma combining vinflunine and gemcitabine compared to gemcitabine alone.

Paclitaxel has been evaluated in several small phase II studies with modest results. In a study of 31 patients with advanced or progressing urothelial cancer, who had previously been treated with at least one systemic chemotherapy, the patients were treated with a 1-hour weekly infusion of 80 mg/m² of paclitaxel. The median number of cycles delivered was three (1 cycle = 4 weeks). Ten percent achieved a response with a median overall survival time of 7.2 months (Vaughn et al, 2002). Two other phase II trials did not replicate the response rates (5% to 7%) with median survival times in the 6-month range (Papamichael et al, 1997; Joly et al, 2009). Docetaxel has also been used in a similar setting as a second-line agent. This regimen demonstrated modest response rates of 13% and median overall survival times of 9 months; however, 60% of patients developed myelosuppression requiring a dose reduction (McCaffrey et al, 1997).

Pemetrexed is a multitargeted antifolate agent. Initial phase II trials were promising, using 500 mg/m² of pemetrexed intravenously every 21 days and noting complete and partial response rates of 6.4% and 21%, respectively, in 47 patients. The median time to disease progression was 2.9 months and median survival was 9.6 months (Sweeney et al, 2006). Grade 3 and 4 hematologic events were thrombocytopenia (8.5%, 0%), neutropenia (4.3%, 4.3%), and anemia (2.1%, 2.1%). However, a phase II trial using the same dose of pemetrexed showed less promising results in 13 patients with advanced disease who had previously received chemotherapy. In this cohort, only one (8%) patient had an objective response. Piritrexim is a synthetic antifolate agent that has also been investigated as a second-line agent. In a phase II trial of 27 patients with advanced, previously treated, urothelial carcinoma, piritrexim showed a 7% objective response rate. Toxicity was not insignificant with dose-limiting myelosuppression in 29% (Roth et al, 2002). Lassiter and associates (2008) obtained similar results in 23 previously treated patients in whom no objective responses were observed, and 2 patients had disease stabilization after 2 to 4 cycles.

Epothilones are nontaxane tubulin polymerization agents derived from fermentation of the myxobacteria *Sorangium cellulosum*. Ixabepilone is a semisynthetic analogue of natural epothilone B. In a phase II trial involving 45 patients with advanced urothelial carcinoma previously treated with either cisplatin or carboplatin-based chemotherapy, ixabepilone was reported to have an overall response rate of 12% and median overall survival of 8 months. Unfortunately, the toxicity profile of this drug was significant, with 27% in the trial experiencing grade 4 toxicity in addition to 1 treatment-related death (Dreicer et al, 2007). Table 94-9 illustrates published single-agent studies in patients with relapsing or progressive disease following first-line chemotherapy.

Multiaгент Second-Line Chemotherapy

For patients who progress following treatment with gemcitabine/cisplatin, second-line MVAC may be an option for select patients. Han and colleagues (2008) reported on a small cohort ($n = 30$) of patients who were treated with MVAC after failing initial therapy with gemcitabine/cisplatin. The overall response rate was 30%, and 6.7% of patients achieved a complete response. Patients who previously had a response to gemcitabine/cisplatin had a 44% response rate compared to a 14% response rate in patients who had not responded to initial therapy.

Multiple studies have investigated the effectiveness of paclitaxel and gemcitabine as a second-line agent. The published response rates of these trials vary widely from 0% to 60%, likely reflecting different dosing and administration schedules (Meluch et al, 2001; Sternberg et al, 2001a; Kanai et al, 2008; Albers et al, 2011). The largest of these trials randomized 102 patients to a temporary 6-cycle course of paclitaxel and gemcitabine compared to prolonged treatment with gemcitabine/paclitaxel. Although there was not a significant difference in overall or progression-free survival between the two groups, the objective response rates were 37.5% and 41.5%, respectively (Albers et al, 2011).

Larotaxel is a next-generation semisynthetic taxane that includes a mechanism of action similar to that of docetaxel and paclitaxel. Larotaxel has been postulated to have advantages beyond other taxanes including activating taxane-resistant tumor cell and the ability to cross the blood-brain barrier (Sessa et al, 2002; Metzger-Filho et al, 2009). In a phase III randomized trial, larotaxel/cisplatin combination therapy was compared to gemcitabine/cisplatin as first-line treatment for locally advanced or metastatic urothelial

carcinoma in 337 patients (Sternberg et al, 2013). The trial was closed early as a result of the sponsor's decision to stop clinical development of larotaxel. At the time of analysis, there was no difference in overall survival between the two study arms, and progression-free survival was worse with larotaxel/cisplatin (5.6 vs. 7.6 months), suggesting that this regimen does not improve outcomes compared to standard gemcitabine/cisplatin.

There is no general consensus regarding the optimal second-line multiagent therapy for patients with progressing and/or metastatic urothelial carcinoma.

Targeted Therapy

Vascular Endothelial Growth Factor Inhibitor Therapy

Vascular endothelial growth factor (VEGF) receptors are expressed in urothelial carcinomas (von Hardenberg et al, 2014). It is well established that VEGF recruits circulating endothelial progenitors, which are critical for angiogenesis, which is essential for tumor growth and metastatic spread (Carmeliet et al, 2000). VEGF expression in both the urine and the blood has been shown to correlate with metastatic potential and disease recurrence (Crew et al, 1999; Fauconnet et al, 2009). Bevacizumab is a humanized monoclonal antibody of VEGF. Bevacizumab has been evaluated in patients with advanced urothelial carcinoma. In a phase II trial by the Hossier Oncology Group, 43 chemotherapy-naïve patients with either metastatic or unresectable urothelial carcinoma received bevacizumab in combination with gemcitabine/cisplatin (Hahn et al, 2011). The overall response rate in this cohort was 72% (19% complete, 53% partial). With a median follow-up of 27 months, median progression-free survival was 8.2 months and median overall survival was 19.1 months. Of note, grade 3 to 4 hematologic toxicity was not insignificant, with neutropenia in 35%, thrombocytopenia in 12%, anemia in 12%, and neutropenic fever in 2%. Three treatment-related deaths were also reported. A phase 3 intergroup study is currently in progress, which aims to define further the role of bevacizumab in combination with gemcitabine/cisplatin in patients with advanced urothelial carcinoma.

Sunitinib is an oral inhibitor of multiple tyrosine kinases, including VEGF receptors. Sunitinib has demonstrated antitumor activity in human bladder cancer models (Sonpavde et al, 2009; Yoon et al, 2011). Sunitinib was reported as demonstrating a partial response in 8% and disease stabilization in 54% of 37 cisplatin-ineligible patients with advanced urothelial carcinoma (Bellmunt et al, 2011). The median progression-free survival was 5.9 months. Much like bevacizumab, sunitinib has been trialed in combination with gemcitabine/cisplatin, but the side-effect profile was unsatisfactory (Galsky et al, 2013). Sunitinib was also studied in a randomized, phase II trial of maintenance therapy following an initial response to standard chemotherapy compared to placebo (Grivas et al, 2014). The study did not achieve the predefined power as a result of poor accrual and premature closure, however the maintenance sunitinib arm did not improve 6-month progression-free survival rates (2.9 vs. 2.7 months, respectively). Sorafenib, a similar multikinase inhibitor, has been studied in combination with gemcitabine/cisplatin but did not demonstrate superiority compared to chemotherapy alone (Krege et al, 2014).

Epidermal Growth Factor Receptor Therapy

Epidermal growth factor receptor (EGFR) has demonstrated overexpression in bladder tumors and the extent of expression has also correlated with stage and grade of tumors (Neal et al, 1990). Cetuximab is a monoclonal antibody to EGFR and it has been approved for colorectal carcinoma. Cetuximab has been studied in the phase II setting in patients with metastatic urothelial cancer who received previous chemotherapy (Wong et al, 2012). A total of 39 patients were randomized to cetuximab with or without paclitaxel. The single-agent cetuximab arm closed after 9 of 11 patients progressed by 8 weeks. Cetuximab did appear to augment the activity of the paclitaxel arm, with an overall response rate of 28.5% and a median

progression-free survival of 115 days. Cetuximab has also been evaluated in combination with gemcitabine/cisplatin in the phase II setting, but did not improve overall survival (Pea, 2012). The oral tyrosine kinase inhibitor (TKI) gefitinib has produced disappointing results today in urothelial carcinoma trials. In a phase II trial of 31 patients with metastatic urothelial carcinoma, gefitinib was largely ineffective, with a median progression-free survival of 2 months; only two patients survived with no disease progression past 6 months (Petrylak et al, 2010). Gefitinib has also been evaluated in combination with gemcitabine/cisplatin and did not improve response rate compared to that of historical controls (Philips et al, 2009). Gefitinib is also being evaluated as maintenance therapy following systemic chemotherapy; however, the results from such studies have not been reported.

Trastuzumab, an anti-Her-2 monoclonal antibody, has been evaluated in several studies. Human epidermal growth factor receptor 2 (HER2)/neu expression in urothelial cancers is variable and may predict a more aggressive phenotype. In 44 patients with HER2/neu-positive tumors, the overall response rate was 70% when combined with paclitaxel, gemcitabine, and carboplatin (Hussain et al, 2007). Trials using trastuzumab either as a single agent in advanced urothelial carcinoma or as a combination agent with concurrent radiation therapy in the bladder-sparing setting are currently underway. Lapatinib is an oral TKI that targets both EGFR and HER2. A phase II trial of lapatinib in 59 patients whose disease progressed on platinum-based chemotherapy demonstrated disease stabilization in 31% of evaluable patients (Wülfing et al, 2009). The median time to disease progression and overall survival was 8.6 weeks and 17.9 weeks, respectively. The median survival was significantly improved in patients whose tumors expressed EGFR and/or HER2. Only one of six patients was able to receive full dosing of lapatinib in combination with paclitaxel because of grade 2/3 gastrointestinal toxicity (Culine et al, 2012). The U.S. Oncology Research network is conducting a randomized discontinuation trial that evaluates salvage therapy with lapatinib in HER2 expressing metastatic urothelial carcinoma. The EORTC is also evaluating lapatinib in combination with gemcitabine/cisplatin in a phase I dose escalation trial. Finally, erlotinib, a TKI to HER1 and HER2 has been evaluated in a neoadjuvant setting before cystectomy in patients with muscle-invasive bladder cancer (Pruthi et al, 2010). Twenty patients were included in this study, of which 25% were pT0 and 35% were downstaged at the time of cystectomy.

Novel Pathways for Targeted Therapy

Multiple alternative pathways have been investigated as potential therapeutic targets in the bladder cancer population including MET, phosphatidylinositol-3 kinases (PI3K), heat shock proteins, cytotoxic T-lymphocyte antigen 4 (CTLA-4), and prostate stem cell antigen (PSCA) (Ghosh et al, 2014). Carbazantinib is an oral chemotherapy agent that targets MET and VEGFR2 and prevents angiogenesis by inhibition of hepatocyte growth factor-induced MET signaling in urothelial cell lines (Cecchi et al, 2012). A phase II trial of carbazantinib is currently underway in patients with metastatic urothelial carcinoma. Ipilimumab is an inhibitor of CTLA-4 (Ghosh et al, 2014). Ipilimumab interrupts CTLA-4 inhibition of T cells and thus allows for cytotoxic T-lymphocyte destruction of tumor cells (Page et al, 2013). A phase II trial of ipilimumab with gemcitabine and cisplatin is currently underway in patients with metastatic urothelial carcinoma. As our understanding of bladder cancer genetics and molecular pathways increases, targeted therapeutics have the potential to take on a greater role in metastatic bladder cancer treatment in the future.

CONCLUSIONS

Optimal treatment of muscle-invasive bladder cancer requires a multidisciplinary approach incorporating urologic oncologists, medical oncologists, and radiation oncologists. Current clinical staging modalities lack the sensitivity and specificity to predict

accurately the final disease stage, which is currently a major limitation to pretreatment decision making. The gold standard therapy for organ-confined muscle-invasive bladder cancer is radical cystectomy with neoadjuvant cisplatin-based chemotherapy. Bladder preservation with chemoradiation therapy has become an increasingly popular option in the muscle-invasive setting and has demonstrated outcomes comparable to those of radical cystectomy in highly selected patients. Despite aggressive surgical therapy, approximately 50% of cystectomy patients will ultimately die of disease.

Meta-analysis from systemic cisplatin-based neoadjuvant chemotherapy trials has demonstrated a modest but statistically significant survival advantage. The evidence for adjuvant chemotherapy is less robust secondary to inadequately powered trials and methodological flaws. Initial response rates with cisplatin-based chemotherapy in the metastatic setting are good; however, durable responses are rare and outcomes for this patient population are dismal. Multiple new second-line chemotherapy trials have been completed or are underway with varying response rates. Newer biologic agents hold promise; however, evidence is currently lacking and more studies are warranted.

Transurethral Resection of Bladder Tumors

Patient Preparation

Surgical Technique

Pelvic Lymphadenectomy

Radical Cystectomy: Male

Radical Cystectomy: Female

Partial Cystectomy

Postoperative Care

According to data available from the American Cancer Society, there was expected in 2015 to be an estimated 74,000 new cases and 16,000 deaths from bladder cancer in the United States (Siegel et al, 2013). This ranks bladder cancer as one of the most common noncutaneous malignancies and accounts for 6% of cancers among men. Without appropriate surgical therapy the disease can be deadly and can impart significant health care costs. Surgical therapy, whether for non-muscle-invasive or muscle-invasive disease requires careful attention to technique, oncologic principles, and a firm understanding of disease pathogenesis.

During the initial evaluation, transurethral resection (TUR) serves to not only establish the pathologic diagnosis and the local extent of the disease, but it should also be viewed as a complete oncologic procedure, especially in the setting of low-grade and non-muscle-invasive tumors. However, in the setting of a muscle-invasive tumor, to achieve adequate local control and to maximize the chance for cure, radical cystectomy with a regional lymph node dissection is necessary.

The history of both TUR and also surgical removal of the bladder dates to the 1800s. Bardenheuer of Germany is credited with performing the first cystectomy in 1887 in a patient with an advanced tumor of the bladder (Stenzl et al, 2005). Around that same time the first modern endoscope was invented through collaboration between Maximilian Carl-Friedrich Nitze and Joseph Leiter. Nitze, another German urologist, and Leiter, an instrument maker, created a tool that throughout the following decades would evolve into the modern instrumentation used today.

The first modern technique for radical cystectomy appeared in 1956 from Paquin and Marshall. In their early description, radical cystectomy in men began with a perineal exploration and dissection of the rectum from the bladder and prostate under direct visualization. Additionally they favored cutaneous ureterostomies for urinary diversion (Paquin and Marshall, 1956). The initial report by Whitmore and Marshall (1956) of surgical outcomes in 100 patients in that same year demonstrated significant morbidity and 17 (17%) postoperative deaths. Refinements during the years have resulted in substantial improvements in both oncologic outcomes and surgical morbidity. A more contemporary analysis of 1142 patients demonstrated only a 0.9% inpatient mortality rate and a 2.7% 90-day mortality rate following radical cystectomy (Shabsigh et al, 2009).

Oncologic outcomes have similarly improved from the 21% to 49% 5-year survival rate reported by Whitmore and colleagues in 1962 (Whitmore and Marshall, 1962) to a 59% 5-year survival rate in a study of 507 patients (Madersbacher et al, 2003) and 66% in the largest report to date of 1054 patients treated at the University of Southern California. In addition to improvements in surgical

technique, the administration of neoadjuvant chemotherapy has been demonstrated to improve survival from a median of 46 months to 77 months (Grossman et al, 2003) and should be considered in all patients with muscle-invasive tumors who are scheduled to undergo radical cystectomy.

TRANSURETHRAL RESECTION OF BLADDER TUMORS

Advances in operative instrumentation have greatly enhanced the ability of urologists to identify, treat, and follow patients with bladder tumors. The approach to a new patient with a bladder tumor mirrors that of any new patient visit, with particular attention paid to those factors most likely to have contributed to the development of bladder cancer. A detailed history and physical examination should be performed. Care should be taken to identify known risk factors including but not limited to tobacco exposure, previous cyclophosphamide chemotherapy, aromatic amines, and phenacetin use. Information regarding surgical implants and valvular heart disease may influence antibiotic prophylaxis and should be obtained and compared to current guidelines. Additionally all patients should be queried regarding either a personal or a family history of bleeding with procedures and the use of anticoagulants, as these questions will be relevant in preparation for surgery. The authors have not observed significant bleeding difficulty in patients who are on aspirin and it is not our routine to stop aspirin therapy; however, we advise caution in patients taking other anticoagulants (e.g., warfarin, heparin, clopidogrel) as these pose a higher bleeding risk.

Physical examination should be thorough and should include palpation of abdomen and suprapubic region noting any palpable mass. A digital rectal examination (DRE) in men can be informative and can raise suspicion of prostatic involvement. Likewise a bimanual examination in women can elucidate anterior vaginal involvement. Routine laboratory studies should be obtained and should include a complete blood count, metabolic panel, coagulation panel, and urinalysis with culture. In the setting of active infection, resection should be delayed until clearance of bacteria with appropriate therapy.

Upper tract imaging should be obtained to complete the diagnostic evaluation and this can include renal ultrasound in conjunction with retrograde pyelogram, computed tomography (CT) urogram (CTU), magnetic resonance imaging (MRI), and rarely intravenous pyelogram. Care should be taken to ensure adequate renal function (glomerular filtration rate [GFR] >60 mL/min) if intravenous iodinated contrast is being considered.

As an alternative, MRI contrast agents can be administered for GFR greater than 30 mL/min but these are contraindicated for those less than 30 mL/min. In the case of muscle-invasive tumors, formal staging evaluation should be obtained inclusive of the chest, abdomen, and pelvis.

Patients will routinely have first undergone cystoscopy in the office with a flexible cystoscopy, allowing for visual confirmation of a mucosal tumor and aiding in surgical planning. At the time of diagnostic cystoscopy, care should be taken to note the location and extent of tumor burden.

Although experienced clinicians have been shown to predict accurately the stage and grade of tumors on follow-up cystoscopy (Herr et al, 2002), adequate tissue sampling must be obtained at baseline even when a low-grade tumor is suspected. In the setting of tumors overlying a ureteral orifice, clinicians should be prepared to perform additional interventions including ureteroscopy, and they may require the use of fluoroscopy at the time of TUR.

TUR of bladder tumors is performed with the aid of a rigid cystoscope. To ensure adequate maneuverability the patient should be positioned in dorsal lithotomy. Based largely on an extrapolation from a randomized study examining antibiotic prophylaxis for TUR of the prostate in 400 patients, which showed a reduction in postoperative bacteriuria (Wagenlehner et al, 2005), the American Urologic Association recommends the routine use of antibiotic prophylaxis for patients undergoing TUR of bladder tumors, and it should be administered within one hour of the procedure.

A thorough visual inspection is then performed using the 30-degree lens to examine the urethra in its entirety and then to perform a preliminary evaluation of the bladder mucosa and ureteral orifices. A visual obturator should be used to minimize trauma

to the urethra during this phase. After initial inspection, a 70-degree lens should be used to completely evaluate the bladder again with particular attention paid to the bladder neck, dome, and anterior wall. If necessary a more acute lens such as a 120-degree can be used if full visualization is not possible otherwise. The location and extent of tumors should be noted.

Resection can then be performed with either monopolar or bipolar electrocautery. Irrigation fluid can either be sterile water or 1.5% glycine in the case of monopolar electrocautery or 0.9% sodium chloride if bipolar current is used. This has the added benefit of lowering the risk of postoperative electrolyte abnormalities as well as mitigating an obturator reflex if the tumor is overlying the lateral walls of the bladder.

The goal of any resection should be the visual eradication of any tumor burden and the assurance of an adequate depth of resection. Utilizing cutting current, a loop electrode is used to resect the tumor inclusive of muscularis propria (Fig. 95-1). Histologically, bladder tumors frequently exhibit growth beyond the visible edge and, as such, resection should include an approximate 2-cm margin of normal-appearing tissue. Wide resection of tumors will ensure completeness whether the tumor has a broad base or a tentacular growth pattern (Fig. 95-2). After resection to visual completion, the bladder should be emptied and a bimanual examination under anesthesia (EUA) should be performed. Accordingly, any palpable lesion should be noted and staged clinically (cT3b).

Tumors may pose specific challenges, and a proper understanding of technique will help mitigate the risk of complications. When tumors are encountered on the lateral wall, there is the risk of an obturator reflex whereby the cautery current stimulates the obturator nerve, causing the ipsilateral leg to adduct. This can lead to

Figure 95-1. A, Broad-based papillary lesion. B, Resection of lesion with loop electrocautery. C, Depth of resection to detrusor muscle.

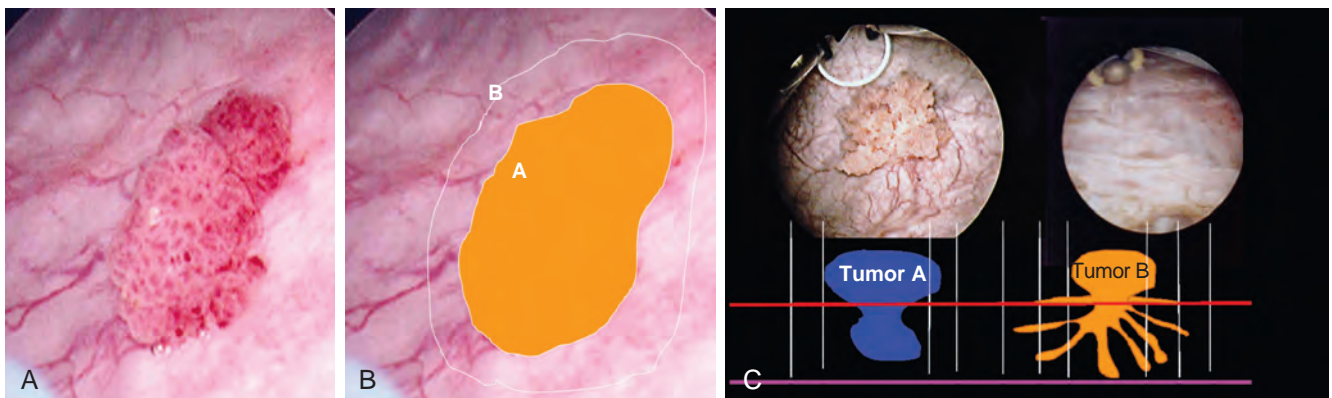

Figure 95-2. A, Papillary bladder lesion. B, Visual boundary of tumor (A) and margin of resection to optimize tumor destruction (B). C, Deep invasion of tumor in broad-based and tentacular pattern.

inadvertent deflection of the instrument laterally and can cause perforation. To lessen this risk, we recommend the following techniques. First, minimize distention of the bladder to the minimum needed to perform the resection. Second, check whether available bipolar cautery may mitigate or eliminate the reflex. Last, if the patient is under a general anesthetic, muscle relaxant can be administered thereby lessening any movement resulting from obturator nerve stimulation. Tumors overlying a ureteral orifice pose another challenge. In this setting, only cutting current should be used and resection strokes should be as quick as possible to minimize the possibility of cauterizing the ureteral orifice closed. **Data suggest routine stenting is not necessary following ureteral orifice resection.** Mano and colleagues found that of 79 patients in whom a ureteral orifice was resected, only 3 (4%) developed hydronephrosis (Mano et al, 2012). Although this retrospective study would suggest stenting is not needed in the case of large resections and extensive cautery, we would suggest that stenting might be useful in the short term, although it may not affect ultimate stricture rates. Finally, tumors located at the dome of the bladder may be difficult to resect because of angulation, distance, and concern for intraperitoneal perforation. The challenges are multifactorial and in some cases difficult to overcome. Minimizing bladder distention and suprapubic pressure, either with your nondominant hand or with that of an assistant, can help maneuver the bladder tumor into a location more amenable to resection. Care should be observed to avoid prolonged cautery, as transmission of heat/energy could potentially occur to adjacent bowel viscera even in the absence of bladder perforation.

Perforation of the bladder may be the natural result of an adequate resection, especially in the setting of advanced tumors (Fig. 95-3). Whereas posterior tumors and those of the dome may result in an intraperitoneal perforation (see Fig. 95-3B), resections elsewhere in the bladder are more likely to result in an extraperitoneal perforation (see Fig. 95-3A). In the event of an extraperitoneal perforation, treatment consists of Foley catheter drainage and observation. However, **large intraperitoneal perforations, although rare, with an incidence of 0.36% in a study of 4144 TURs (Golan et al, 2010), can lead to significant morbidity.** Findings during resection suggestive of an intraperitoneal rupture include loss of

bladder distention, visualization of a defect posteriorly or at the dome, and palpable distention of the abdomen. When suspected, confirmation can be obtained with a cystogram at the same setting. In the presence of an intraperitoneal rupture, treatment consists of abdominal exploration, meticulous inspection of the bowel, and repair of the injury with both a Foley catheter and abdominal drainage.

Although data would suggest little to no effect on progression rates, adjuvant intravesical chemotherapy has demonstrated efficacy in reducing recurrences (Kurth et al, 1997). A meta-analysis of 18 randomized controlled trials for a pooled cohort of 3103 patients showed that a single dose of intravesical chemotherapy (e.g., Mitomycin-C, epirubicin) within 24 hours following TUR of non-muscle-invasive bladder tumor resulted in a 13% absolute reduction in tumor recurrence from 50% to 37% yielding a number needed to treat of 7.2 (Abern et al, 2013). Caution should be applied, however, and adjuvant therapy should only be administered in the absence of perforation. In the setting of high-grade non-muscle-invasive disease, bacille Calmette-Guérin therapy remains the most active agent but should not be administered in the immediate postoperative setting. Rather, a waiting period of 2 to 4 weeks should be observed and a lack of gross hematuria should be confirmed before administration.

PATIENT PREPARATION

In advance of surgical therapy for bladder cancer, appropriate pre-operative staging and medical evaluation should be performed. **Patients with adequate renal function and an absence of allergy to iodinated contrast can be staged with CT of the chest, abdomen, and pelvis.** In instances where renal function is impaired, MRI can be substituted. This allows for assessment of distant and regional disease spread and can guide the use of neoadjuvant chemotherapy. Although studies have been conducted examining novel agents for the detection of lymph node metastasis (Birkhäuser et al, 2013) and comparing MRI and CT accuracy (Vargas et al, 2012), CT currently remains the most common modality for staging. A retrospective analysis of 100 patients by Baltaci and colleagues (2013)

Figure 95-3. A, Extraperitoneal bladder rupture during transurethral resection (TUR) of a bladder tumor. B, Intraperitoneal bladder rupture during TUR of a bladder tumor with subsequent intraperitoneal leakage of irrigant and urine. (A and B, © 2009 Memorial Sloan Kettering Cancer Center.)

demonstrated an accuracy of 72% and 86% for the detection of perivesical invasion and lymph node metastasis, respectively. In a smaller study of 16 patients comparing MRI to CT imaging accuracy in determining final T stage, CT was correct in 63%, overstaged in 31%, and understaged in 6% (Vargas et al, 2012).

After confirmation before surgery of localized disease, patients should undergo routine medical evaluation to maximize health status. Comorbidities such as coronary artery disease, smoking-related lung disease, and peripheral vascular disease will commonly be encountered. After medical optimization, regardless of preferred urinary diversion, enterostomal therapy should be used for stoma marking. Although rare, patients should be made aware of the possibility of an ileal conduit urinary diversion even in the case of a planned continent diversion. Careful marking of the ostomy site to avoid interference, both in a standing and in a seated position, is performed to maximize appliance fit and to minimize stomal irritation. If stomal therapists are not available, the surgeon should be familiar with marking strategies and should perform these while the patient is awake and wearing typical clothing.

Mechanical bowel preparation was historically used in the hope of mitigated anastomotic leak, abdominal, and wound infection rates in patients undergoing bowel surgery. However, the results of two large randomized trials in colorectal surgery have brought into question this assumption. Ren and colleagues found, in their study of an enhanced recovery pathway following colorectal surgery, that those who did not undergo a bowel preparation, among other modifications, were no more likely to experience a complication (9.4% vs. 9.7%) and had similar rates of anastomotic leak (Ren et al, 2011). Another large study of 380 patients who underwent colorectal surgery with or without mechanical bowel preparation showed that wound infection rates (prep vs. no prep 6.4% vs. 5.7%), anastomotic leak (prep vs. no prep 3.7% vs. 2.1%), and abdominal abscess (prep vs. no prep 1.1% vs. 1%) were similar (Zmora et al, 2003). Further study in radical cystectomy patients undergoing ileal conduit urinary diversion demonstrated similar findings (Xu et al, 2010). Additionally a study of 40 patients undergoing radical cystectomy with ileal urinary diversion randomized to either 3-day bowel preparation or overnight fasting showed a lower incidence in prolonged ileus (10% vs. 5%) if bowel preparation was not used (Hashad et al, 2012). For this reason we advise against routine bowel preparation for patients undergoing radical cystectomy with urinary diversion, especially if only ileal segments are to be used.

To enhance further the return to bowel function, the μ opioid receptor antagonist alvimopan should be administered 30 to 90 minutes before surgery, as it has been studied and it demonstrates a benefit in both functional bowel recovery and length of hospitalization. The results of a phase III multicenter trial of alvimopan administered 30 to 90 minutes before bowel resection and twice daily thereafter indicated that those who received this drug exhibited lower rates of postoperative ileus (7.3% vs. 15.7%) and a time decrease of 6.2 to 5.2 days for a written discharge order to be pro-

vided (Ludwig et al, 2008). A phase IV study examining the same drug in radical cystectomy patients demonstrated a 2.63-day reduction in hospital stays, lower rates of total parenteral nutrition for postoperative ileus (10% vs. 25%), and a cost savings of \$2340 to \$2640 per patient (Kauf et al, 2014).

Although we do not advise on the routine use of oral antibiotic prophylaxis as an adjunct to mechanical bowel preparation, **intravenous antibiotics should be administered within 1 hour of surgical incision.** The choice of antibiotic should be customized to local bacterial susceptibility patterns and should include both gram-positive coverage (skin flora) and gram-negative aerobes and anaerobes (distal small bowel and large bowel flora). Generally a broad-spectrum cephalosporin such as cefoxitin will provide adequate coverage. Last, in the absence of significant bleeding, high-risk patients should undergo both mechanical thromboembolic prophylaxis (stockings and pneumatic compression) and pharmacologic prophylaxis before the induction of general or spinal anesthesia. Extended prophylaxis in the postoperative period has also been shown to decrease thromboembolic events. A prospective study of 703 patients randomized to either 8 days or 28 days of pharmacologic prophylaxis after abdominal or pelvic surgery showed that those treated for 4 weeks had an 82.4% reduction in the incidence of major venous thromboembolism (0.8% vs. 4.6%) without an increase in bleeding complications (Kakkar et al, 2010).

Patient positioning is vital to provide adequate exposure and to minimize the risk of related complications. Male patients should be placed supine with the flexion point of the table at the level of the anterior superior iliac spine (Fig. 95-4A). Flexion to 15 degrees is usually adequate and can be lessened as necessary if there is a history of spinal fusion or lumbar injury. In women, a low lithotomy position with the aid of stirrups or the use of spreader bars provides access to the vagina. In female patients, table flexion is generally not possible. The operative field should be inclusive of the abdomen from the level of the xiphoid to the upper portion of the thighs. The genital organs, including the vagina in women, and the perineum should be prepared as well. A solution containing 10% povidone-iodine is recommended, as preparations containing chlorhexidine gluconate should be avoided when used on genital skin.

SURGICAL TECHNIQUE

A lower midline incision is made sharply extending distally from the level of the symphysis pubis to the umbilicus superiorly. Frequently an infraumbilical incision provides adequate exposure but can be extended cephalad as needed (Fig. 95-4B). Ensuring incision of the abdominal fascia in the midline aids in both fascial closure and in helping to prevent inadvertent release of the rectus abdominis from its tendinous insertion at the level of the pubis. Upward retraction of the umbilicus (toward the ceiling) aids in the identification of the linea alba. After the midline is identified, the fascia

Figure 95-4. Positioning of the patient in the supine position with the bed flexed to 15 degrees (A). An incision is made in the midline from 2 cm above the umbilicus to just above the level of the pubis (B).

Figure 95-5. Mobilization and division of the umbilicus.

Figure 95-6. Mobilization of the root of the small bowel mesentery and the left colon.

is divided and the space of Retzius is entered. Blunt dissection is performed to release the bladder from the pelvic sidewall attachments bilaterally. This is carried in a cephalad direction to the level of the vas deferens in men and the round ligament in women. At this point a peritoneotomy is made lateral to either medial umbilical ligament and the urachus is controlled and divided (Fig. 95-5). The peritoneum is incised lateral to the medial umbilical ligaments bilaterally to the level of the internal inguinal rings at which point the vas deferens in men and the round ligaments in women will be identified and are divided.

Attention is then turned to the bowel mobilization to achieve adequate exposure of the great vessels and the ureters. On the right side the white line of Toldt is incised and carried around the cecum where then the posterior peritoneum is incised to allow mobilization of the root of the small bowel mesentery. On the left side the white line of Toldt is likewise incised, and a window is created below the sigmoid colon mesentery to communicate with the right-sided posterior peritoneotomy. This space will later be used to transpose the left ureter to the right lower quadrant for urinary diversion (Fig. 95-6).

With the aid of a self-retaining retractor such as a Bookwalter, exposure is maximized and the bowel retracted cephalad. Communication with the anesthesiologist at this point is vital to ensure that inadvertent compression of the vena cava has not resulted. A moistened laparotomy pad or pads should be placed behind retractor blades to protect the abdominal contents. After adequate exposure is achieved, the bilateral ureters are dissected free from their attachments beginning a few centimeters above where they cross the iliac arteries to the level of the detrusor hiatus. Care should be used to ensure that adequate ureteral adventitia is maintained. The superior vesical artery should be ligated and divided before completing the ureteral dissection as this aids in maximizing ureteral length. The ureter is then controlled with either suture ties or suture ligature and is divided.

Although controversial, the distal ureteral margin can be sent for frozen section analysis to evaluate for the presence of urothelial carcinoma. Although studies have shown a correlation between

findings of carcinoma in the ureteral margin and subsequent upper tract recurrence (Schumacher et al, 2006), an impact on survival has not been well established (Raj et al, 2006). Additionally the study by Raj and colleagues indicated that despite sequential resection to achieve a negative margin in 48 instances of an initial positive ureteral margin, upper tract recurrence was not eliminated (Raj et al, 2006). According to surgeon preference, temporary ureteral catheters directed off the surgical field can be used to maintain urinary flow during the remainder of the procedure, or the ureters can be temporarily ligated to avoid spillage of urine into the operative field.

PELVIC LYMPHADENECTOMY

Pelvic lymphadenectomy can be performed at this time or after removal of the bladder specimen according to surgeon preference. The anatomic boundaries of a standard template dissection consist of the genitofemoral nerves laterally, the internal iliac artery medially, Cooper ligament inferiorly, and the point at which the ureter crosses the common iliac artery superiorly (Fig. 95-7A). In cases of advanced disease, an extended dissection inclusive of the entire common iliac lymph node packet and the presacral lymph node packet can be obtained (Fig. 95-7B). Although further extension cephalad to include the para-aortic packet to the level of the inferior mesenteric artery has been studied in bladder cancer, none have demonstrated any additional staging information beyond a dissection from the common iliac arteries distally (Bochner et al, 2004, Bruins et al, 2014). Care should be taken during lymphadenectomy to avoid injury to the obturator nerve and to ensure control of lymphatics at the caudal and cephalad extremes (Fig. 95-7C) and when complete to confirm that no residual lymphoid tissue remains in the operative field (Fig. 95-7D). Surgical quality as measured by nodal yield has demonstrated a survival benefit in bladder cancer. Herr (2004) and colleagues found that in patients in whom at least 10 lymph nodes were removed, 5-year survival improved from 44% to 61%. Later an examination of 1260 patients

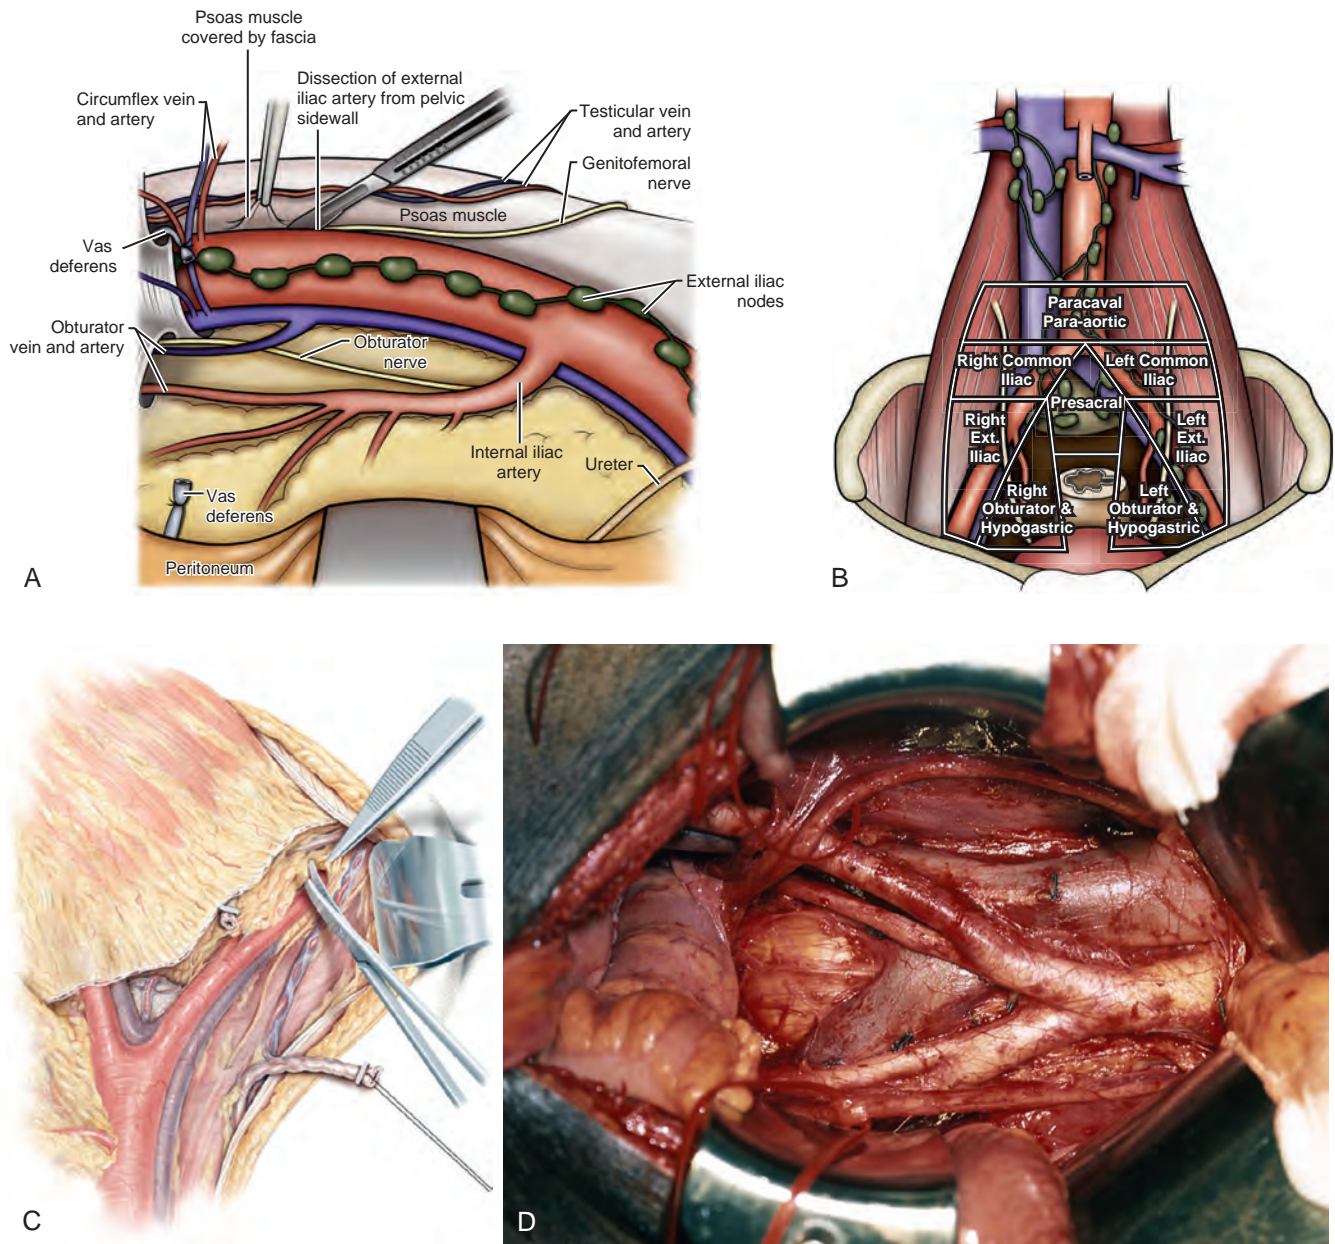

Figure 95-7. A, Standard pelvic lymph node dissection. B, Distributions of the eight node packets from an extended pelvic and retroperitoneal lymph node dissection. C, Meticulous pelvic lymph node dissection. D, Completed extended pelvic lymph node dissection.

in the Surveillance, Epidemiology, and End Results data set with lymph node metastatic bladder cancer showed that for those who had more than 10 lymph nodes removed, overall survival also improved from a median of 13 months if 1 to 5 nodes were removed to 23 months if 10 or more were removed (Wright et al, 2008).

Completion of the pelvic lymphadenectomy aids in the exposure and identification of the vascular pedicles to the bladder (Fig. 95-8). Control of the main branches to the bladder, including the superior, middle, and inferior vesical arteries, can be achieved with the aid of a vascular stapler (see Fig. 95-8B), surgical clips (see Fig. 95-8A), or vascular sealing instruments.

RADICAL CYSTECTOMY: MALE

After completely ligating the lateral vascular pedicles, attention is turned to the posterior dissection. The rectal cul-de-sac is identified and the peritoneum is incised where it overlies the seminal vesicles

(Fig. 95-9A and B). If there is a large tumor at the base of the bladder, care must be observed to ensure an adequate margin of resection at this point. The rectum is dissected free with either blunt dissection or sharp dissection in the midline and is carried to the level of the prostate, at which point Denonvilliers fascia is encountered and incised. In cases of advanced disease, previous pelvic radiation, or reactive fibrosis from previous resection or intravesical chemotherapy, difficulty in developing this plane may be encountered. In such instances blunt dissection should not be performed, as this may cause inadvertent injury to the rectum. Instead, under direct visualization, sharp dissection should be performed with care taken to maintain rectal integrity. If a rectal injury is encountered, primary repair with or without flap coverage and/or bowel diversion should be performed (Kozminski et al, 1989). After release of the rectum in the midline, dissection is carried laterally and the posterior vesical pedicles are identified (Fig. 95-10A). Similar to the lateral pedicles, they can be controlled with surgical clips, ties, vascular staplers, or sealing instruments (Fig. 95-10B). Care should be

Figure 95-8. A, Application of clips to the lateral vascular pedicle of the bladder. B, Application of an endovascular stapler to the lateral vascular pedicle of the bladder. (B, © 2009 Memorial Sloan Kettering Cancer Center.)

Figure 95-9. A, The posterior plane beyond the cul-de-sac, which separates the bladder and prostate from the rectum. B, Division of the peritoneum overlying the rectum in the cul-de-sac.

Figure 95-10. A, Exposure of the posterior vascular pedicle of the bladder for ligation. B, Ligation and division of the posterior pedicle. (A, © 2009 Memorial Sloan Kettering Cancer Center.)

taken, however, if sealing instruments are used, as the heat they generate can transmit and may injure the rectum if in close proximity. With a gloved finger surgeons should shield the rectum from the tips of such instruments while in use.

After completion of the posterior dissection, the urethra should be palpable and at this point attention can be turned to the anterior dissection in a fashion similar to a radical prostatectomy. The endopelvic fascia overlying the levator muscles is incised sharply, allowing for identification of the confluence between the urethra and the dorsal venous complex. Ligation and division of the dorsal venous complex (Fig. 95-11) allows for visualization of the anterior urethra, which is then incised.

If continent ileal neobladder urinary diversion is planned, adequate urethral length must be maintained and a frozen section analysis of the urethral margin performed. In a study of 436 patients who underwent eight cutaneous or orthotopic diversions, urethral recurrence occurred in 7.9% of patients at 5 years and at a median of 1.6 years following radical cystectomy (Freeman et al, 1996). Additionally the study demonstrated that patients with an orthotopic diversion were at lower risk of urethral recurrence (4% vs. 10%), although the reason is unclear. In another study of 118 male patients following radical cystectomy, no patients with a negative intraoperative urethral frozen section had a urethral recurrence at 10 years of follow-up (Lebet et al, 1998). A large study examining the usefulness of preoperative prostatic urethral biopsy in predicting final urethral margin status demonstrated poor correlation (68%), but very high negative predictive value (100%) if the intraoperative frozen section was negative (Kassouf et al, 2008). We therefore recommend that in the presence of a positive urethral margin, orthotopic neobladder should not be performed and the patient should be made aware of this possibility during preoperative counseling.

The role of preservation of the neurovascular bundles, unlike in radical prostatectomy, remains controversial in radical cystectomy. A technique analogous to radical prostatectomy (Fig. 95-12A and B) can be applied; however, the functional outcomes remain

Figure 95-11. Division of the dorsal venous complex.

Figure 95-12. A, Nerve-sparing radical cystectomy in the male patient. B, Separation of the plane between the prostatic capsule and the neurovascular bundle.

Figure 95-13. Non-nerve-sparing radical cystectomy in the male.

significantly worse. In a report of erectile dysfunction in sexually active men treated with radical cystectomy, [Zippe and colleagues \(2004\)](#) found in their series of 49 men that only 6 of 16 (38%) who underwent nerve-sparing surgery were naturally potent after surgery, and only 7 of 49 (14%) were potent when including all patients (nerve-sparing and non-nerve-sparing). These results do not differ significantly from reports of men who underwent non-nerve-sparing cystectomy as reported by [Asgari and colleagues \(2013\)](#). In that study of 81 sexually active men, they found that at 1 year only 9.8% (ileal conduit) to 35% (neobladder) regained function sufficient for vaginal penetration and maintenance of erection until the completion of intercourse ([Asgari et al, 2013](#)). Among men who underwent nerve sparing, age, similar to the radical prostatectomy series, is a strong predictor of functional recovery with a drop from 62% potency for men aged 40 to 49 years to 20% for those 70 to 79 years ([Schoenberg et al, 1996](#)). Additionally, in their report of 101 patients only 5 (5%) suffered a local recurrence; however, caution should be noted as one was a patient with pT2 disease. The risks and benefits of nerve sparing should be judged according to preoperative sexual function and disease burden. **Non-nerve sparing (Fig. 95-13)** is the preferred choice in advanced disease and in patients with preexisting erectile dysfunction.

Additional efforts have been used to improve sexual functional outcomes including subtotal resection of the prostate. Described techniques include leaving the prostate in its entirety or sparing the prostatic capsule and/or the seminal vesicles. These approaches have largely been studied in the context of orthotopic neobladder urinary diversion. In the setting of nonurothelial cancers, Spitz and colleagues showed that both erectile and ejaculatory function could be maintained in 3 of 4 patients ([Spitz et al, 1999](#)). In another report, Colombo and colleagues showed excellent erectile function outcomes in all of the 27 patients and no instances of local recurrence; however, follow-up was limited to only 32 months ([Colombo et al, 2004](#)). There is, however, concern because of the high rate of occult prostate cancers in radical cystectomy specimens. This has been shown to be as high as 41% in larger series ([Revelo et al, 2004](#)). Despite this, in highly selected patients excellent local control can be maintained. In a study of 100 patients without evidence of prostate cancer preoperatively and negative frozen section at surgery, only 5 (5%) developed local recurrence, although distant metastasis did develop in 31 patients ([Vallancien et al, 2002](#)). To achieve such outcomes, however, proper patient selection is paramount. Preoperative evaluation should include DRE, prostate specific antigen (PSA) testing, transurethral prostatic resection, and intraoperative frozen section analysis. In the setting of PSA or DRE abnormality prostate biopsy should be done in advance of surgery.

RADICAL CYSTECTOMY: FEMALE

Radical cystectomy in the female patient historically included total anterior pelvic exenteration inclusive of the bladder, urethra, anterior vagina, uterus, and cervix. This allows for adequate resection and is vital in the presence of a positive EUA or if there is concern for anterior vaginal wall invasion (cT4a). It should also be noted that compared to men, women present with more advanced disease ([Kluth et al, 2013; Mitra et al, 2014](#)). Additionally, in the study by Kluth and colleagues of more than 8000 patients, in multivariable analysis female gender was an independent risk factor for death from disease (hazard ratio = 1.17 [range 1.05 to 1.31], $P = .005$) ([Kluth et al, 2013](#)). For this reason, anterior pelvic exenteration remains the gold standard of therapy. As discussed later, however, in patients with low-stage disease (cT1 and cT2) where orthotopic neobladder is considered, vaginal and urethral sparing is necessary.

As described earlier, the initial steps for bowel mobilization, anterior bladder mobilization, and ureteral dissection are the same in men and in women with the exception of the gonadal vessels. In female patients the ovarian vessels should be identified during the

bowel mobilization and ligated with a 2-0 silk suture distally, and both a 2-0 silk suture ligature and a tie proximally, and then divided. Anterior pelvic exenteration begins with identification of the posterior cervical fornix (Fig. 95-14A), and the vaginal cuff is incised at this position (Fig. 95-14B). After gaining entry to the vaginal canal, the lateral and posterior vascular pedicles to the bladder can be controlled easily. According to surgeon preference, vascular staplers, sealing devices, or clips are applied and the specimen can be dissected free inclusive of the uterus, cervix, anterior vaginal cuff, and bladder. The urethral meatus is then incised, either antegrade from the pelvis or externally from the vaginal introitus, and the specimen is removed (Fig. 95-15A and B). Care should be taken to ensure that sufficient vaginal mucosa is maintained above the urethral meatus to allow for closure of the vaginal defect in subsequent steps. Because of the vascular nature of the female pelvis and the sinusoidal nature of the vascular pedicles as they pass over the lateral vaginal wall, care is needed to ensure hemostasis. To com-

plete the vaginal closure with a 2-0 polyglactin suture, the posterior vaginal wall must be released from the rectum (Fig. 95-15C). The posterior vaginal flap is then closed to the corresponding mucosae of the introitus in a clamshell fashion to maintain vaginal girth at the cost of some vaginal length. **Bothersome drainage of peritoneal fluid will result if the vaginal closure is not watertight, and an interrupted closure is preferred.** A vaginal packing is then placed with the dual purpose of distending the vagina and tamponading any residual vaginal wall hemorrhage (particularly useful if vaginal sparing is performed; discussed later) and aids in the identification of unrecognized defect in the closure. This packing should be removed within two postoperative days.

In the absence of bladder neck involvement and the presence of low-stage disease ($\leq T2$), orthotopic neobladder can be considered. This necessitates urethral sparing with adequate length proximal to the striated sphincter and anterior vaginal wall sparing to provide support to the neobladder. As described previously, the

Figure 95-15. A, Posterior vaginal wall and defect at the level of the introitus after en bloc removal of the bladder in an anterior pelvic exenteration in the female patient. B, Intraoperative photograph of the introital defect. C, Coverage of the introital defect with a flap made from the posterior vaginal wall.

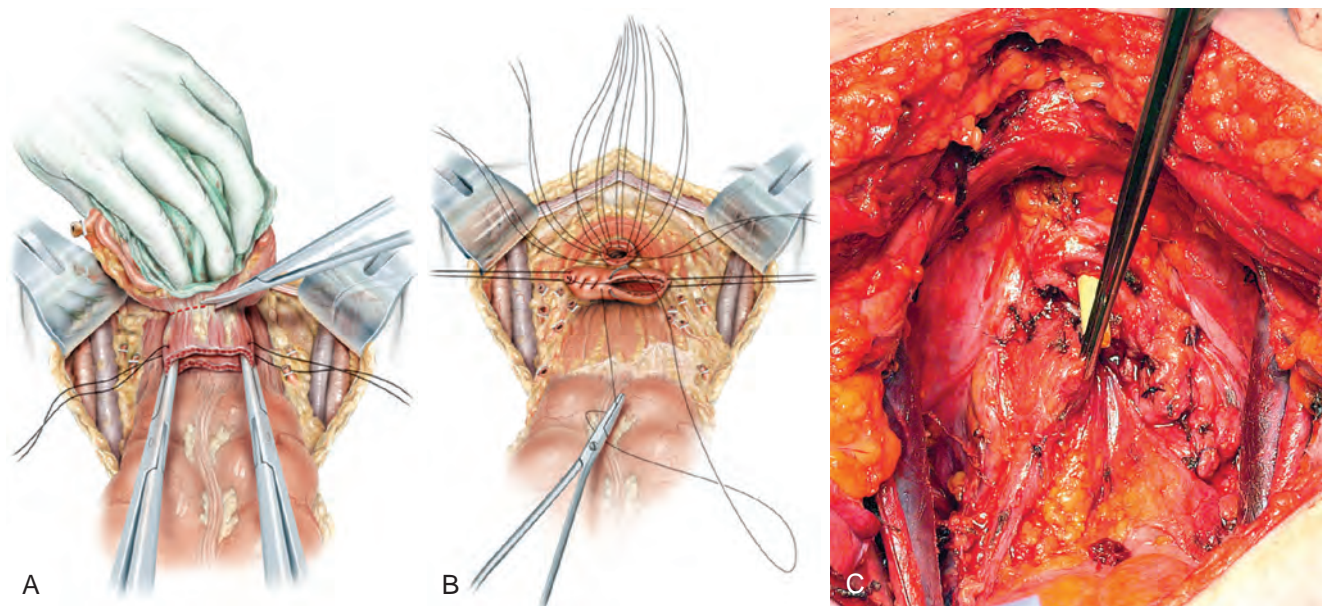

Figure 95-16. A, Circumferential division of the vaginal cuff from the attachments to the cervix. B, Closure of the vaginal cuff and placement of the urethral anastomotic sutures. C, Intraoperative photograph of the completed repair.

lateral vascular pedicles are intimate with the lateral wall of the vagina and to control these vessels properly they must be separated from the vagina before ligation. This can be achieved either after removal of the cervix and uterus at the level of the cervical fornix (Fig. 95-16A) or while they are still in place. A vaginal packing during this step can aid in defining the plane of separation between the bladder and the anterior vaginal wall in the midline. After development this space is extended laterally, separating the lateral vascular pedicles from the lateral vaginal wall. To ensure that an adequate bladder margin is maintained, the vessels should not be divided until the midpoint of the lateral vaginal wall, in the anterior posterior plane, has been reached. This dissection is carried to the level of the bladder neck, which can easily be identified by use of the Foley catheter balloon as a guide. Maintaining the integrity of the striated sphincter, the specimen is removed at this level (Fig. 95-16B) and a frozen section of the urethral margin is sent and managed in the same fashion as in male neobladder candidates. Again, if the urethral margin analysis demonstrated malignancy, orthotopic diversion is contraindicated. The vaginal apex is closed with 2-0 polyglactin sutures and urethral anastomotic sutures placed (see Fig. 95-16B and C).

PARTIAL CYSTECTOMY

Consideration for bladder-sparing surgery in the setting of muscle-invasive urothelial carcinoma requires proper patient selection. For those with solitary lesions of small size and who lack concurrent carcinoma in situ (CIS), results from partial cystectomy are similar to those of radical cystectomy. In an analysis of 37 such patients treated at the MD Anderson Cancer Center, nine (24%) developed either a muscle-invasive and/or metastatic recurrence; however, the 5-year overall and the disease-specific survival rates were 67% and 87%, respectively (Kassouf et al, 2006). In a population-based matched cohort study examining partial versus radical cystectomy when matched for surgical quality (number of lymph nodes removed) and clinicopathologic features, partial cystectomy was equivalent in terms of overall and cancer-specific survival (Capitanio et al, 2009). Patients initially treated with partial cystectomy can be salvaged with radical cystectomy; however, survival is significantly worse for locally advanced disease at the time of salvage. In patients with organ-confined disease, 5-year

survival is 60% whereas it is only 7% for extravesical disease (Bruins et al, 2012).

In the select patients who are candidates for partial cystectomy, preoperative preparation includes counseling regarding the possibility of radical cystectomy and the discussion of urinary diversion, as it is possible that an adequate margin will not be possible or extravesical disease will be encountered. Partial surgical removal includes pelvic lymphadenectomy, as described earlier, as well as anterior bladder mobilization. Cystostomy is performed in an area away from the tumor. The tumor is then excised including the underlying bladder wall and perivesical fat with a mucosal margin of 1 to 2 cm and confirmation of resection adequacy with frozen section analysis. If necessary, the ureteral orifice or intramural ureter can be excised and a reimplantation performed. After excision of the tumor the cystostomy is closed with 2-0 polyglactin suture in 2 or 3 layers, and an instillation of fluid via a Foley catheter is performed to ensure a watertight closure. Copious warm water irrigation of the surgical field is performed to minimize the possibility of pelvic seeding. A closed suction drain should be placed and the cystostomy closure interrogated with a cystogram on postoperative day 7 before removal of the Foley catheter.

Although rare, primary adenocarcinoma arising from the urachus requires additional resection. These tumors are most commonly confined to the dome of the bladder although they may grow by direct extension to involve other areas. A circumferential incision around the umbilicus is made and extended toward the pubis. Complete excision includes the umbilicus, the urachus, and the dome of the bladder with a visual margin free from tumor (Fig. 95-17). Again this is confirmed with frozen section analysis, and additional resection may be necessary. Bladder augmentation with the use of an intestinal segment can be performed if bladder capacity is significantly reduced.

POSTOPERATIVE CARE

Radical cystectomy is a complex procedure involving not only the genitourinary but also the gastrointestinal tract because of urinary diversion. In addition to this complexity, patients are frequently elderly and present with significant comorbidities. Although major complications are infrequent (13%) any complication remains common (64%) with the most frequent being gastrointestinal

Figure 95-17. Resection of an adenocarcinoma of the urachus. (© 2009 Memorial Sloan Kettering Cancer Center.)

(29%) or infectious (25%) (Shabsigh et al, 2009). Postoperative efforts are necessarily directed at minimizing the possibility of complications and maximizing the return of normal physiology. Immediately after surgery, laboratory results including cell count, electrolytes, and renal function are assessed and fluid dynamics are monitored. Frequently patients will require initial observation in intensive care or stepdown units. Routine nasogastric suction is not needed; however, it is considered in compromised mentation or known issues with airway protection. As discussed earlier, thromboembolic prophylaxis should be continued in the postoperative setting in the absence of hemorrhage. In addition to pharmacologic measures, early ambulation should be used and pulmonary exercise (incentive spirometry) with deep breathing and coughing should be encouraged.

Delayed return of bowel function frequently prolongs hospitalization after radical cystectomy. Medications such as alvimopan can be used, which has been shown to improve return of bowel function and to shorten hospital stays. Additional postoperative steps to enhance recovery include neostigmine (with telemetry monitoring) to encourage further the return of bowel function, promotility suppositories, stress ulcer prophylaxis, antiemetics, early enteral feeding in the absence of nausea and/or emesis, and avoidance of narcotic pain medication (ketorolac and acetaminophen unless contraindicated) (Djaladat and Daneshmand, 2013).

ACKNOWLEDGMENTS

The authors acknowledge Drs. John Stein, Kent Berglund, and Harry W. Herr whose work on the previous version of this chapter was invaluable in the preparation of the current text. In particular, the

KEY POINTS

- Bladder cancer is a common cancer associated with high cost and frequent fatality.
- Radical cystectomy offers excellent survival for organ-confined disease.
- TUR is both diagnostic and therapeutic, especially for low-grade tumors.
- Perioperative intravesical chemotherapy decreases recurrence rates by 13%.
- A standard template pelvic lymphadenectomy includes the genitofemoral nerves laterally, the internal iliac artery medially, Cooper ligament inferiorly, and the point at which the ureter crosses the common iliac artery superiorly.
- Ureteral margin frozen section aids in predicting upper tract recurrence but sequential resection to a negative margin might have no impact.
- Nerve-sparing radical cystectomy aids in the preservation of sexual function and is performed in a manner analogous to radical prostatectomy.
- Subtotal prostatic resection can further enhance return of sexual function but should only be offered in select patients in whom the risk of occult prostate cancer is low.
- Vaginal sparing is appropriate in the absence of locally advanced tumors and allows for orthotopic urinary diversion.
- Partial cystectomy can be considered in rare, solitary urothelial tumors without concomitant CIS.
- Urachal adenocarcinomas are treated with en bloc resection of the umbilicus and dome of the bladder.
- Enhanced recovery protocols can aid in the recovery of normal physiology after radical cystectomy and can shorten hospital stays.

Surgery of the urinary bladder and distal ureter often involves significant extirpative as well as reconstructive techniques, demanding skill and experience from the urologic surgeon. As a result of these technical challenges, bladder surgery is associated with significant complication rates. In an attempt to minimize the morbidity of open surgery, minimally invasive techniques for surgery of the urinary bladder have been introduced and refined. Procedures that previously required large open incisions now can be performed through a limited number of keyhole incisions.

Laparoscopic and robotic techniques can be used for essentially every bladder operation. In most cases, improved cosmetic results are accompanied by reductions in associated pain, duration of hospitalization, and recovery times. Technology continues to drive the field forward, and natural orifice transluminal endoscopic surgery and laparoendoscopic single-site surgery (LESS) techniques have been employed to reduce further the incisions and morbidity associated with surgery of the urinary bladder. This chapter describes conventional laparoscopic, robotic, and LESS approaches to surgery of the distal ureter and the bladder, focusing on indications, techniques, complications, and outcomes (Box 96-1).

BLADDER DIVERTICULECTOMY

Diverticula of the urinary bladder can be congenital, acquired, or, rarely, iatrogenic in nature. Bladder diverticula are characterized by a herniation of the urinary mucosa through a weakness or absence of the detrusor muscle. Bladder diverticula have scattered and/or nonfunctional residual muscle fibers, which can impair emptying and contribute to urinary stasis. Congenital bladder diverticula include periureteral diverticula, also referred to as Hutch diverticula, which can be associated with vesicoureteral reflux (VUR). Posterior urethral valves and neurogenic bladder are also commonly associated with diverticula. Various conditions, including Williams syndrome, Menkes disease, and prune-belly syndrome, can include multiple diverticula in the absence of outlet obstruction. Acquired diverticula are most commonly associated with bladder outlet obstruction (BOO), with resultant high-pressure voiding and subsequent diverticula formation. Traditionally, diverticulectomy has been approached through an open low midline incision. However, with the evolution of minimally invasive techniques, complex and multiple bladder diverticula can be managed laparoscopically or robotically (Fig. 96-1). In combination with endoscopic manage-

ment of BOO and bladder calculi, these techniques often result in reduced morbidity to the patient.

Evaluation and Surgical Indications

The first step in evaluation of a bladder diverticulum involves the determination of the underlying cause responsible for the diverticulum. Most often, this involves confirmation of BOO and may involve determination of urinary flow rate, postvoid residual urine volume, and urodynamic studies. Underlying BOO must be identified and addressed, typically at the time of diverticulectomy. Cystoscopy is an essential component of the evaluation of bladder diverticula. Diverticula size, number, and location are recorded, and proximity to the ureteral orifices is noted. The bladder outlet is evaluated for evidence of prostatic hypertrophy, presence of an intravesical component, bladder neck contracture, or stricture. Ultrasound scan of the prostate can be useful to assess prostate volume, which can aid in determining the appropriate outlet procedure, when indicated. In conjunction with urinary cytology, thorough inspection of all diverticula is mandatory to rule out malignancy. Small diverticula can be managed with cystoscopic fulguration. Voiding cystourethrography defines the location, size, and number of diverticula and can diagnose concomitant reflux or urinary stasis. Upper tract imaging with intravenous urography (IVU) or computed tomography (CT) urogram is useful to evaluate the relationship of the ureter to the diverticulum to prevent injury during surgery as well as identify any hydronephrosis resulting from obstruction. Urinalysis and culture is essential before surgical intervention.

Small, asymptomatic bladder diverticula without associated complications can be observed. Diverticulectomy is indicated for large diverticula with incomplete emptying, chronic or repeated urinary tract infection, bladder calculi, or pain. Occasionally, a bladder diverticulum can result in ureteral reflux or obstruction, requiring diverticulectomy and ureteral reimplantation. Transitional cell carcinoma within a bladder diverticulum is an indication for partial cystectomy. Any BOO must be addressed either before or at the time of diverticulectomy.

Surgical Approach

Since Czerny's first description of diverticulectomy in 1897 (Knappenberger et al, 1960), the surgical treatment of bladder diverticula

BOX 96-1 Minimally Invasive Surgery of the Bladder and Distal Ureter

Bladder diverticulectomy
 Ureteral reimplantation
 Boari and bladder advancement flaps
 Enterocystoplasty
 Mitrofanoff and Monti tube
 Vesicovaginal and ureterovaginal fistula

 Radical cystoprostatectomy and extended lymphadenectomy
 Female radical cystectomy
 Simple/supratrigonal cystectomy
 Bladder stone and foreign body removal

Figure 96-1. Computed tomography urogram of the abdomen/pelvis of a patient with Williams syndrome and four bladder diverticula. Laparoscopic bladder diverticulectomy of diverticula can be performed in a single setting in experienced hands. Contiguity between true bladder (B) and two posterior bladder diverticula (D) is demonstrated.

has evolved from open surgery, to endoscopic procedures, to laparoscopic and robotic techniques. Transperitoneal laparoscopic bladder diverticulectomy (LBD) was first introduced in 1992 (Das, 1992; Parra et al, 1992) and later in the pediatric setting (Kok et al, 2000). Numerous subsequent reports demonstrated the reproducibility of the technique via a transvesical as well as extravesical approach (Nadler et al, 1995). Extraperitoneal laparoscopy may limit the risk of visceral injury and intra-abdominal urine leak. The transperitoneal approach provides a wide and generous working space and superior access for posterior diverticula. LBD has also been described for tumor within a diverticulum (Tai et al, 2007; Thwaini et al, 2008; Wang et al, 2008) and is described in more detail in the section on laparoscopic and robotic partial cystectomy.

Similarly, robotic bladder diverticulectomy (RBD) has been described in adults and children as an effective minimally invasive alternative providing similar benefits (Myer and Wagner, 2007; Rao et al, 2007; Macejko et al, 2008; Tareen et al, 2008; Meeks et al, 2009). The robotic approach mimics the laparoscopic technique, aids the surgeon without extensive laparoscopic experience, and provides a comfortable ergonomic platform for working in the deep pelvis. The choice of surgical approach for bladder diverticulectomy depends on numerous factors, including the number and location of diverticula, proximity of the diverticulum to the ureter, and the

Figure 96-2. Selective catheterization of the bladder diverticulum with a Council tip catheter. A Foley catheter in the bladder permits selective distention of the diverticulum to aid in diverticular identification and dissection. Ureteral catheterization aids in ureteral identification to avoid injury. (Modified from Porpiglia F, Tarabuzzi R, Cossu M, et al. Sequential transurethral resection of the prostate and laparoscopic bladder diverticulectomy: comparison with open surgery. *Urology* 2002;60:1045.)

need for concomitant ureteral or bladder outlet surgery. Complex and multiple diverticula requiring concomitant ureteral reimplantation can be handled via a laparoscopic or robotic approach, provided that the surgeon has sufficient experience and skill.

Various alternative approaches to laparoscopic diverticulectomy have been described in attempts to minimize morbidity further. Transvesical pneumovesicoscopic diverticulectomy has been described involving the cystoscopic establishment of carbon dioxide pneumovesicum, with subsequent transabdominal trocar placement directly into the bladder (Badawy et al, 2008; Marte et al, 2010). LESS has been employed to address bladder diverticula as well via a transabdominal (Stolzenburg et al, 2011) as well as a transvesical approach (Roslan et al, 2012).

Technique

Before port placement, flexible cystoscopy can be performed for ureteral catheterization if necessary. Selective catheterization of the diverticulum can be performed by placing a Council tip catheter over a guidewire into the diverticulum and a separate Foley catheter into the bladder proper for selective filling and intraoperative identification of bladder diverticula (Nadler et al, 1995; Porpiglia et al, 2002; Khonsari et al, 2004), as seen in Figure 96-2.

Alternatively, real-time illumination of the diverticulum with a flexible cystoscope is a useful aid in identifying the diverticulum, as described later (Parra et al, 1992; Jarrett et al, 1995; Nadler et al, 1995). In our experience, this is particularly valuable in patients with multiple diverticula, in which separate catheterization of each diverticulum is not practical. Intravesical methylene blue also has been described as an aid to identify the bladder neck during robotic diverticulectomy (Moore et al, 2012). After pneumoperitoneum is established by a closed or open technique, trocars for RBD and LBD are positioned as depicted in Figure 96-3.

If approached transperitoneally, LBD or RBD begins with an incision of the peritoneum overlying the diverticulum. For complex, large, or multiple diverticula, the bladder can be mobilized: The peritoneum is incised medial to the obliterated umbilical ligament bilaterally, the urachus is divided, and the bladder is “dropped” posteriorly allowing for entry into the space of Retzius. The 10-mm LigaSure device (ValleyLab, Boulder CO) can be used during LBD,

Figure 96-3. A, Robotic bladder diverticulectomy. A 12-mm port at the umbilicus is employed for the endoscope. Two 8-mm robotic trocars are placed 10 cm inferolaterally at the pararectus location. At the surgeon's discretion, assistant ports are placed as needed; options include a 5-mm trocar (placed halfway in between the camera and robotic trocar) and/or a 12-mm trocar (two fingerbreadths above the anterior superior iliac spine). If needed, an additional 8-mm trocar can be used for the fourth arm of the robot two fingerbreadths above the contralateral anterior superior iliac spine. B, Laparoscopic bladder diverticulectomy. A 10-mm port at the umbilicus is employed for the endoscope. For a right-handed surgeon, working ports include a 12-mm and 5-mm trocar, at the right and left pararectus location, respectively. An optional 5-mm trocar can be placed approximately 2 cm cephalad and medial to the anterior superior iliac spine (depicted in green).

and a combination of monopolar and bipolar cautery instrumentation is employed during RBD. With the aid of either selective catheterization and filling or cystoscopic transillumination, the diverticulum is identified (Fig. 96-4). Peridiverticular adhesions are transected, and the mouth of the diverticulum is circumscribed and excised. Constant vigilance is required to prevent injury to the ureter or ureteral orifice. If necessary, a transvesical approach can be

employed. The bladder is opened, and the diverticulum is pulled into the bladder, circumscribed, and excised. In either approach, the bladder is closed anatomically in two layers with absorbable suture. During LBD, freehand intracorporeal suturing can be employed. Alternatively, an Endo Stitch device (Covidien, Mansfield, MA) can be used as a suturing aid. An Endo GIA (Covidien) stapling device can also be used for excision; however, this carries with it the theoretical risk of bladder stone formation (Kerbl et al, 1993). The bladder is filled to ensure watertight closure. A Jackson-Pratt drain is placed via one of the trocar sites to avoid an unnecessary additional incision. If needed, ureteral reimplantation secondary to reflux, obstruction, or iatrogenic injury is performed as described in the following section.

LESS has been demonstrated as an approach to diverticulectomy with excellent cosmetic outcomes (Roslan et al, 2012). After single-site access in the transabdominal approach, the operation follows the same basic steps as described earlier. During transvesical single-site diverticulectomy, the procedure begins with cystoscopy-guided placement of a single port access device transvesically, followed by the establishment of pneumovesicum (Roslan et al, 2013). The diverticular neck is circumscribed with a monopolar scissors or hook, and the diverticulum is excised. Retraction can be aided by transurethral and/or cystoscopic instrumentation. The defect is subsequently closed, and the specimen is extracted (Roslan et al, 2013).

Surgical management for BOO can be performed concomitantly, either immediately before or after bladder diverticulectomy. Surgical management includes transurethral resection of the prostate (TURP), potassium titanyl phosphate laser vaporization, holmium laser enucleation, and photoselective vaporization (Iselin et al, 1996; Grönlund et al, 1998; Porphiglia et al, 2002; Faramarzi-Roques et al, 2004; Shah et al, 2006; Kural et al, 2009). If endoscopic management is performed after diverticulectomy, a suprapubic catheter should be placed to avoid perforation at the bladder-closure suture lines. Similarly, laparoscopic or robotic simple prostatectomy can be performed at the time of LBD or RBD (Magera et al, 2008).

Postoperative care involves Jackson-Pratt drain removal, typically 48 hours postoperatively. Cystography is performed to rule out a bladder leak before Foley catheter removal, at approximately 1 week after surgery.

Outcomes and Complications

Minimally invasive techniques are effective in treating bladder diverticula. LBD is effective in reducing postvoid residual to normal values (<50 mL) (Fig. 96-5). LBD has been demonstrated to be effective even in patients with complex pathology, including multiple diverticula and giant diverticula measuring 30 cm (Khonsari et al, 2004). RBD has been demonstrated to be effective with excellent perioperative outcomes and average hospital stays of approximately 2 to 3 days (Altunrende et al, 2011; Eyraud et al, 2013).

Minimally invasive management of a bladder diverticulum and BOO with concomitant LBD and TURP has been demonstrated to be superior compared with open bladder diverticulectomy and transvesical prostatectomy. Laparoscopic BD and TURP is associated with reduced blood loss, analgesic requirements, and shorter hospital stay, but longer OR times (Porphiglia et al, 2002, 2004). No complications were noted with either approach, and postoperative urinary flow rates were equivalent. In a series of 13 patients undergoing extravesical LBD without concurrent management of BOO, Abdel-Hakim and colleagues (2007) experienced only one complication in the form of extravasation from the suture line that resolved with conservative management. Sequential holmium laser enucleation of the prostate and laparoscopic extraperitoneal bladder diverticulectomy has been performed with good outcomes (Shah et al, 2006). RBD and concomitant photoselective vaporization of the prostate also has been described with excellent outcomes and limited morbidity (Kural et al, 2009). Complications of minimally invasive bladder diverticulectomy are similar to complications encountered during open bladder diverticulectomy and include ureteral injury, infection, urinary extravasation, urinary fistula, wound infection, and bowel injury.

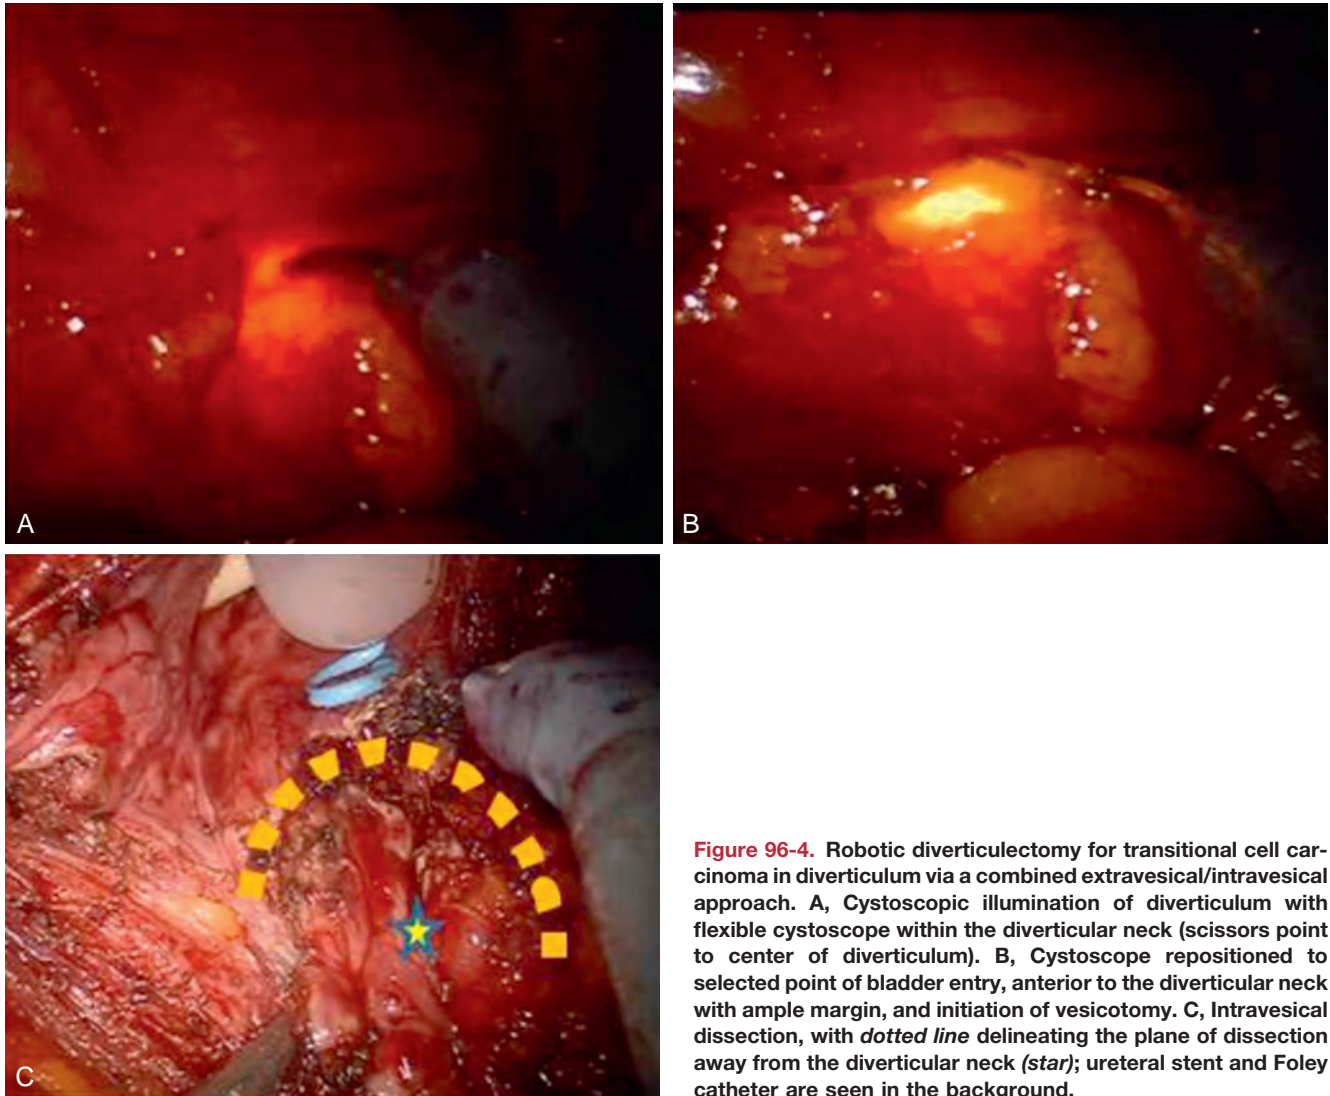

Figure 96-4. Robotic diverticulectomy for transitional cell carcinoma in diverticulum via a combined extravesical/intravesical approach. A, Cystoscopic illumination of diverticulum with flexible cystoscope within the diverticular neck (scissors point to center of diverticulum). B, Cystoscope repositioned to selected point of bladder entry, anterior to the diverticular neck with ample margin, and initiation of vesicotomy. C, Intravesical dissection, with *dotted line* delineating the plane of dissection away from the diverticular neck (*star*); ureteral stent and Foley catheter are seen in the background.

Figure 96-5. Significant reductions in postvoid residual urinary volumes document the efficacy of laparoscopic bladder diverticulectomy for complex bladder diverticula. (Data from Richstone and Kavoussi, unpublished data, 2007.)

Conclusions

LBD and RBD are effective approaches for complex diverticula. Bladder outlet or ureteral surgery can be managed in the same setting using endoscopic and/or laparoscopic techniques. Transvesical and LESS approaches are feasible and may speed recovery and improve cosmetic results.

KEY POINTS: BLADDER DIVERTICULECTOMY

- Laparoscopic and robotic bladder diverticulectomy is an effective approach for even complex diverticula.
- Bladder outlet or ureteral surgery can be managed in the same setting using endoscopic and/or laparoscopic techniques.

URETERAL REIMPLANTATION

Ureteral reimplantation is traditionally performed via an open low midline or Pfannenstiel incision. Laparoscopic ureteroneocystostomy is a well-described and effective alternative, but it requires significant laparoscopic experience and intracorporeal suturing skills. In a drive to limit scar number and size, LESS ureteral reimplantation may offer cosmetic benefits, albeit with even greater technical demands on the surgeon. In contrast, the robotic-assisted laparoscopic approach offers simplified suturing and reconstructive

Figure 96-6. Robotic extravesical ureteral reimplantation. A tunnel is made in the detrusor muscle for the ureter, completing the antirefluxing mechanism. A, After anastomosis of the spatulated ureter to the bladder mucosa, detrusorrhaphy is initiated. B, Completed extravesical reimplantation. (From Gundeti MS, Kojima Y, Haga N, et al. Robotic-assisted laparoscopic reconstructive surgery in the lower urinary tract. *Curr Urol Rep* 2013;14:333.)

aspects of this procedure, while offering the cosmetic and recovery benefits of minimally invasive surgery.

Evaluation and Surgical Indications

Indications for ureteroneocystostomy include VUR, ureteral obstruction, and transection. The specific indications for ureteral reimplantation in the setting of VUR are beyond the scope of this chapter and are discussed elsewhere in this text. Ureteral obstruction can be secondary to stone disease and inflammatory, infectious, iatrogenic, and traumatic etiologies as well as benign or malignant mass lesions. When medical and/or endoscopic approaches fail or are deemed insufficient for the given pathology, ureteral reimplantation is indicated.

VUR is evaluated and graded with voiding cystourethrography. In the setting of ureteral obstruction, stricture length can be evaluated with a combination of excretory and retrograde urography. An estimation of the length of the diseased segment is critical in determining whether ureteral length would allow for a ureteroneocystostomy or warrant more complex reconstruction. In addition, the anatomic location of the strictured segment needs to be assessed because upper ureteral strictures require more complex reimplantation techniques. A retrograde pyelogram can be useful to define strictured segments anatomically or locate the position of ureteral tumors. Nuclear renography is useful to document obstruction and, when necessary, to evaluate function when there is a history of longstanding or severe obstruction or reflux. In appropriate patients, it is critical to consider and rule out malignancy with urinary cytology, endoscopy, and appropriate imaging.

Technique

Laparoscopic and robotic ureteral reimplantation can be performed via an extravesical or intravesical approach. Refluxing or nonrefluxing reimplantation techniques have been described. The approach should be tailored to patient age, pathology, anatomy, and surgeon preference.

Nonrefluxing Ureteral Reimplantation

Several investigators demonstrated the feasibility of laparoscopic correction of VUR in animal studies (Atala et al, 1993; Schimberg et al, 1994; McDougall et al, 1995). Laparoscopic extravesical Lich-Gregoir ureteral reimplantation in humans followed shortly thereafter (Ehrlich et al, 1994; Reddy and Evans, 1994; Janetschek et al, 1995). Typical port site placement is similar to that employed for bladder diverticulectomy (see Fig. 96-3).

The extravesical Lich-Gregoir technique can be performed via a conventional laparoscopic or robotic-assisted approach. The ureter is identified medial to the obliterated umbilical ligament, and the

overlying peritoneum is incised. The ureter is mobilized to the ureterovesical junction, preserving periureteric tissue to ensure adequate vascular supply. The location of the proposed tunnel is determined with the bladder filled with saline and care taken to avoid creating a “kinking” tunnel. A 5:1 tunnel-to-ureteral diameter is maintained. Taking care to avoid perforation of the bladder mucosa, the detrusor muscle is incised to create a sufficient trough. The ureter is placed within the trough, and the detrusor is closed over it, using a series of interrupted 3-0 absorbable sutures (Fig. 96-6) (Reddy and Evans, 1994; Hedican et al, 1999; Lakshmanan and Fung, 2000; Gundeti et al, 2008).

The transvesical Cohen cross-trigonal approach has been employed by several authors using the pure laparoscopic and the robotic technique (Gill et al, 2001; Peters and Woo, 2005; Yeung et al, 2005; Kutikov et al, 2006). By avoiding the peritoneal cavity, the transvesical approach has the potential to limit complications associated with the transabdominal approach. A three-trocar configuration accommodates either the pure laparoscopic or the robotic technique.

As originally described by Gill and colleagues (2001), the procedure is performed with two 5-mm transvesical trocars, glycine irrigation within the bladder, and visualization throughout the procedure with a transurethral 24-Fr resectoscope. An electrosurgical Collins knife is used to incise the bladder mucosa and create the cross-trigonal trough, and the detrusor is then sewn over the ureter laparoscopically. This procedure was modified by Yeung and colleagues (2005) using carbon dioxide insufflation of the bladder and a midline trocar for laparoscopic, rather than cystoscopic, visualization of the procedure. In pediatric patients, two 3-mm trocars can be used for working ports, a 5-mm midline trocar can be used for the camera, and an 8-Fr pediatric feeding tube can be placed in the urethra for intermittent suctioning (Kutikov et al, 2006). Similarly, a three-trocar robotic transvesical approach to cross-trigonal reimplantation has been described (Peters and Woo, 2005). After circumferential incision around the ureteral orifice, the ureter is mobilized by incising periureteral attachments. The native hiatus is reduced with 4-0 absorbable suture, and a cross-trigonal submucosal tunnel and new mucosa hiatus are created. The ureter is advanced and anchored with several interrupted 4-0 absorbable sutures, and the periureteral mucosa is sutured to the bladder mucosa with 5-0 absorbable stitches (Fig. 96-7).

Refluxing Ureteral Reimplantation

Laparoscopic or robotic ureteral reimplantation for benign ureteral stricture disease or select cases of ureteral malignancy is commonly performed in a refluxing manner (Seideman et al, 2009). We routinely perform laparoscopic ureteral reimplantation using a three-trocar approach (Fig. 96-8).

Figure 96-7. A-C, Robotic transvesical cross-trigonal ureteral reimplantation.

Figure 96-8. Ureteral reimplantation. Trocar placement for left ureteral reimplantation includes a 10-mm umbilical camera port and a 12-mm working port placed halfway between the umbilicus and the symphysis pubis. A 5-mm working port is placed at the lateral edge of the rectus muscle at the level of the umbilicus on the ipsilateral side of the procedure.

The distal ureter is dissected, and the diseased segment is excised. In cases of transitional cell carcinoma, it is important to excise the entire distal ureter including the ureteral orifice. To this end, we recommend taking a “formal bladder cuff,” which can be performed entirely laparoscopically or robotically. The bladder is opened at the dome, and the ureteral hiatus and distal ureter are formally excised from within the bladder. The hiatus is sutured closed with 2-0 Vicryl sutures, and the anterior cystostomy is similarly closed. A Foley catheter is left in place for 7 days postoperatively. A new ureteral hiatus is created at the dome of the bladder, and the spatulated ureter is reimplanted with 4-0 absorbable sutures in a running or interrupted fashion (Reddy and Evans, 1994; Fugita and Kavoussi, 2001). The posterior wall of the bladder can be sutured to the psoas tendon (psoas hitch) with 2-0 Prolene sutures to take any tension off of the ureteral reimplantation. Minimally invasive management of longer ureteral defects is discussed in the next section on psoas hitch and bladder advancement flaps.

Outcomes and Complications

Clinical experience with laparoscopic and robotic ureteroneocystostomy continues to evolve. Small feasibility studies prevail; however,

a few larger studies with intermediate-term follow-up data support the efficacy of the approach.

Lakshmanan and Fung (2000) described 71 extravesical ureteral reimplantations in 47 patients for management of VUR. No patients experienced subsequent obstruction or recurrent reflux. Complications were minimal and included three ureteral injuries, two of which required open reimplantation. Yeung and colleagues (2005) performed 30 laparoscopic transvesical cross-trigonal reimplantations in 16 patients. The mean operative time was 112 minutes for unilateral cases and 178 minutes for bilateral cases. Two patients had subcutaneous and scrotal emphysema that resolved spontaneously. The radiographic success rate was 96%.

In the largest reported series in adult patients, Seidman and colleagues (2009) reported on 45 patients undergoing laparoscopic ureteral reimplantation for benign and malignant pathology. The median hospital stay was 3 days, and estimated blood loss was 150 mL. Minimal complications were experienced, including urinary extravasation at the anastomotic site in three patients, which was conservatively managed. With a mean follow-up time of 2 years, the authors reported a 96% success rate.

Rassweiler and colleagues (2007) compared 10 patients undergoing laparoscopic ureteral reimplantation with 10 patients treated by open techniques. In this small series, the laparoscopic approach was associated with less blood loss, lower analgesic requirements, less time to oral intake, shorter hospital stay, and shorter convalescence time. Similarly, Simmons and colleagues (2007) retrospectively compared 12 laparoscopic versus 34 open ureteral reimplantation procedures, demonstrating a reduced blood loss and shorter hospitalization associated with laparoscopy. Complication rates and ureteral patency rates were equivalent at a mean follow-up of nearly 2 years. Several authors have documented the feasibility of robotic-assisted ureteral reimplantation (Yohannes et al, 2003; Uberoi et al, 2007; Patil et al, 2008). The robotic technique recapitulates the laparoscopic technique and may facilitate the learning curve for reconstructive procedures requiring intracorporeal suturing.

More recently, LESS surgery has emerged as a technique with the potential for improved cosmetic outcomes and perhaps reduced pain and convalescence. LESS ureteroneocystostomy has been reported, but larger series are needed to validate the efficacy and safety of the approach (Desai et al, 2009). Roslan and colleagues (2012) reported a case of a LESS ureteroneocystostomy. Khanna and associates (2012) reported on three cases of LESS ureteral reimplantation. With a median follow-up of 29 months, none of the three patients required revision or had recurrent stricture disease. There are clear technical challenges, and most surgeons reporting on LESS ureteral reimplantations have had broader experiences in LESS nephrectomy and other types of LESS reconstructive surgeries.

Conclusions

Laparoscopic and robotic ureteroneocystostomy are viable alternatives to open surgery. Extravesical and transvesical approaches can

be employed to perform refluxing or nonrefluxing ureteral reimplantation. Evolving data support the efficacy of this approach for VUR and ureteral obstruction or transection. In the future, LESS may provide an even less invasive approach to ureteroneocystostomy, possibly reducing disfigurement and morbidity.

KEY POINTS: URETERAL REIMPLANTATION

- Laparoscopic and robotic ureteroneocystostomy are viable alternatives to open surgery.
- Extravesical and transvesical approaches can be employed to perform refluxing or nonrefluxing ureteral reimplantation.
- Evolving data support the efficacy of this approach for VUR, as well as ureteral obstruction or transection.
- In the future, LESS surgery may provide an even less invasive approach to ureteroneocystostomy, possibly reducing disfigurement and morbidity.

PSOAS HITCH AND BLADDER ADVANCEMENT FLAPS

When faced with minimal distal ureteral loss, simple ureteroneocystostomy is sufficient to reestablish urinary continuity. However, more extensive gaps require more complex reconstructive techniques. The Boari bladder flap was introduced for bridging larger gaps between the ureter and bladder in 1894 in a canine model and in humans in 1947 (Fugita and Kavoussi, 2001). Laparoscopic Boari flap was first performed in a porcine model and in humans in 2001 (Fergany et al, 2001; Fugita and Kavoussi, 2001). This procedure can be performed with or without a psoas hitch to anchor the bladder to gain additional length and avoid anastomotic tension. Defects of the distal third ureter are routinely bridged with this technique. The robotic approach can ease the technical burdens of extensive intracorporeal suturing required for Boari flap creation (Schimpf and Wagner, 2008; Allaparthi et al, 2010). More recent literature has documented the feasibility of laparoscopic Boari flap to reach the proximal ureter and/or renal pelvis in select cases. When this approach is insufficient, ureteroureterostomy, transureteroureterostomy, autotransplantation, or ileal ureteral substitution can be considered.

Evaluation and Surgical Indications

Laparoscopic or robotic Boari flap with or without psoas hitch is indicated when the degree of ureteral loss precludes simple ureteroureterostomy or ureteroneocystostomy. Preoperative evaluation of ureteral obstruction includes antegrade and/or retrograde urography to estimate the extent of disease and aid in planning for the surgical approach. Ultimately, intraoperative findings dictate the need for Boari flap and/or psoas hitch. Nuclear renography is indicated if impaired renal function is suspected. Cystoscopy, urinalysis, and urinary cytology is performed to rule out malignancy.

Technique

Laparoscopic or Robotic Boari Flap

Laparoscopic Boari flap was first described in humans by Fugita and Kavoussi (2001) in a series of three patients with distal ureteral obstruction. The robotic-assisted laparoscopic approach was first reported several years later (Schimpf and Wagner, 2008). Trocar placement for laparoscopic reimplantation and Boari flap or advancement flap is depicted in Figure 96-8. Trocar placement for the robotic approach is identical to that used for diverticulectomy, as seen in Figure 96-3. With either approach, the procedure begins by incising the ipsilateral white line of Toldt and identifying the ureter as it crosses the iliac vessels. The ureter is mobilized distally, and the diseased segment is excised, ensuring that the distal margin is well vascularized and healthy. If indicated, a distal margin is sent for frozen section, and the ureter is spatulated. The bladder is filled

with 200 mL of normal saline and mobilized by incising the peritoneum medial to the obliterated umbilical ligaments bilaterally and transecting the urachus. Blunt dissection allows the bladder to “drop” posteriorly, and the space of Retzius is entered. Ligation of the contralateral bladder pedicle with an Endo GIA stapling device and psoas hitch using 2-0 absorbable suture often can provide enough mobilization to perform a ureteroneocystostomy (Modi et al, 2005; Schimpf and Wagner, 2008). If this maneuver does not suffice, a Boari flap or bladder advancement flap is performed. Using electrosurgical scissors or a 10-mm LigaSure device, an anterior bladder flap is created beginning approximately 2 cm from the bladder neck and extending to the ipsilateral bladder dome; the apex of the flap is approximately 2 cm, and the base of the flap is approximately 4 cm (Fig. 96-9) (Fugita and Kavoussi, 2001). Care should be taken to confirm that the base of the flap is wide enough to ensure adequate vascularity. The spatulated ureter is anastomosed to the apex of the flap with interrupted 4-0 absorbable suture. After placement of a 7-Fr double-pigtail catheter over a guidewire, the flap is closed in a running fashion in two layers with 4-0 and 2-0 absorbable suture or with the assistance of an EndoStitch device. The bladder is filled to 300 mL to identify any sites of anastomotic leakage, and a Jackson-Pratt drain is placed through the 5-mm trocar site. The Jackson-Pratt drain is typically removed in 48 hours, and the Foley catheter is removed in 1 week after cystography confirms no urinary leakage. The ureteral stent is removed in 4 weeks.

Laparoscopic or Robotic Bladder Advancement Flap

Laparoscopic bladder advancement flap was first described by Lima and colleagues (2005) as a simplified alternative to a Boari flap. The bladder is opened with a transverse incision, placed one third of the distance from the dome to the bladder neck (Fig. 96-10). The spatulated ureter is anastomosed to the bladder flap in a fashion similar to a Boari flap, described previously.

Laparoscopic “Mega-Boari” Flap

Proximal ureteral strictures generally have required ureteral substitution or autotransplantation. We have had success with “mega-Boari” flap formation, successfully mobilizing a bladder flap to the level of the proximal ureter or renal pelvis, in six patients (Richstone and Kavoussi, unpublished data, 2007). The kidney is mobilized completely, and, when necessary, descensus and nephropexy is performed to gain length. The ureter or renal pelvis is divided at the proximal aspect of the diseased segment. The bladder is mobilized by incising the peritoneum bilaterally, medial to the obliterated umbilical ligaments. The posterior peritoneum is incised to free the posterior wall of the bladder. The contralateral ureter is identified and protected. The urachus is then divided, and the contralateral bladder pedicle is divided. The bladder flap is created with a transverse cystotomy incision along the lateral and posterior bladder wall above the trigone (Fig. 96-11). Extreme care is taken to avoid injury to the contralateral ureteral orifice. A 2.5-cm flap is developed from the posterior surface of the bladder extending toward the anterior aspect. The free edge of the flap is transposed superiorly toward the kidney. To gain length for the flap, several stepwise 1-cm incisions are made along both of the edges of the bladder flap. In this fashion, the “mega-Boari” flap can reach the level of the spatulated renal pelvis without tension. Anastomosis is performed with running 4-0 Vicryl suture, and the posterior bladder tube is closed with running 2-0 absorbable suture over a 7-Fr × 28-cm double-J ureteral stent. The remaining bladder defect was closed with running 2-0 absorbable suture.

Laparoscopic Single-Site Surgery Boari Flap

LESS Boari flap has been described and may improve cosmetic results. Either a homemade or a manufactured multichannel LESS port is used. Alternatively, multiple standard trocars can be introduced through a single site, typically the umbilicus. Robotic-assisted

Figure 96-9. Laparoscopic Boari flap. A, An anterior flap is created beginning 2 cm from the bladder neck and extending to the bladder dome. B, The spatulated ureter is anastomosed to the apex of the flap with interrupted 4-0 absorbable suture. C, The flap is closed in a running fashion. (Modified from Fugita OE, Kavoussi L. Laparoscopic ureteral reimplantation for ureteral lesion secondary to transvaginal ultrasonography for oocyte retrieval. *Urology* 2001;58:281.)

LESS approach also can be used. After access is obtained, the procedure is performed identically to laparoscopic and robotic flap creation (Khoder et al, 2011).

Outcomes and Complications

The first clinical series of laparoscopic ureteral reimplantation with Boari flap was reported in 2001 and involved three patients (Fugita and Kavoussi, 2001). The approach was demonstrated to be feasible with a mean operative time of 220 minutes and estimated blood loss ranging from 400 to 600 mL. With a mean follow-up period of 11 months, all patients had resolution of obstruction. Castillo and colleagues (2005) reported a slightly larger series of laparoscopic Boari flap in eight patients. Operative times (mean 157

minutes), blood loss (mean 124 mL), and hospital stay (mean 3 days) further validated the feasibility of the technique. Two complications occurred, including one pulmonary embolism and one episode of urinary leakage at the anastomosis requiring laparoscopic repair. With a mean follow-up of 18 months, all patients had resolution of obstruction. Seideman and colleagues (2009) reported the largest single-center series of laparoscopic Boari flap in 21 of 45 patients undergoing laparoscopic ureteral reimplantation with significant follow-up (mean 24 months). Two patients underwent distal ureterectomy for transitional cell carcinoma. Median length of stay was 3 days, and median estimated blood loss was 150 mL. Complications included small bowel obstruction in one patient, *Clostridium difficile* colitis and respiratory distress in one patient, and urinary leakage in two patients that was managed conservatively in

Figure 96-10. Laparoscopic bladder advancement flap. A, After spatulation of the ureter, a transverse opening is made on the anterior surface of the bladder one third from the bladder dome. B, As the incision is widened, the advancement flap is extended to the ureter. C, The ureter is anastomosed to the advancement flap. (Modified from Lima GC, Rais-Bahrami S, Link RE, et al. Laparoscopic ureteral reimplantation: a simplified dome advancement technique. *Urology* 2005;66:1307.)

both cases. In a multi-institutional series of 30 patients undergoing laparoscopic Boari flap, excellent outcomes were achieved (Castillo et al, 2013). In that series, mean operating room time was 161 minutes, and mean estimated blood loss was 123 mL with no intraoperative complications or conversion to open surgery. Post-operative complications occurred in 17% of patients, with a success rate of 97% at a mean follow-up of 32 months. Similarly, excellent results have been reported with a robotic approach, albeit with smaller series to date (Allaparthi et al, 2010; Musch et al, 2013).

Conclusions

Laparoscopic and robotic approaches to psoas hitch, Boari flap, and bladder advancement flap for patients with moderate distal ureter loss have been demonstrated to be an effective alternative to open

surgical techniques. Outcomes appear favorable compared with open series.

KEY POINTS: PSOAS HITCH AND BLADDER ADVANCEMENT FLAPS

- Outcomes appear favorable when compared with open series.

Figure 96-11. Laparoscopic mega-Boari flap for proximal ureteral stricture. After renal mobilization and transection of the ureter at the level of obstruction, the posterior bladder is scored for incision on the outer posterior aspect of the bladder (A). Viewed anteriorly, the flap is mobilized; *dashed lines and translucency* indicate incision and flap on the outer posterior aspect of the bladder (B). The anastomosis is created and the posterior aspect of the bladder flap is closed (C). (Data from Richstone and Kavoussi, unpublished data, 2014.)

ENTEROCYSTOPLASTY

Augmentation cystoplasty is a well-established surgical option for a patient with a poorly compliant bladder with a small capacity who has failed conservative management. [Docimo and colleagues \(1995\)](#) were the first to perform a purely laparoscopic gastrocystoplasty in a single patient. Although the procedure took almost 11 hours and involved a 13-day hospital course, the feasibility of the technique was demonstrated. Subsequently, [Gill and associates \(2000\)](#) described laparoscopic ileocystoplasty, sigmoidocystoplasty, and cecocoloplasty with bowel anastomosis done extracorporeally. Over the past decade, ileocystoplasty has emerged as the most widely employed technique. Reports of laparoscopic, robotic, and LESS bladder augmentation have documented the reproducibility of these techniques by purely intracorporeal and partly extracorporeal approaches.

Evaluation and Surgical Indications

Candidates for augmentation cystoplasty include patients with poorly compliant bladders with small capacity who are capable of self-catheterization ([Elliott et al, 2002](#)). Most commonly, these patients have a neurogenic bladder secondary to spinal dysraphism or other anatomic abnormalities. All patients should undergo video-urodynamics before augmentation. An ultrasound scan should be obtained to rule out hydronephrosis, which should be evaluated before surgery. All patients must be physically and psychologically competent and willing to perform self-catheterization. Contraindications to either open or minimally invasive augmentation include renal insufficiency, renal tubular acidosis, and gastrointestinal disease including short gut syndrome, inflammatory bowel disease, and liver failure ([Elliott et al, 2002](#)).

Technique

The procedure begins with cystoscopic evaluation and placement of bilateral open-ended or single-J ureteral catheters, which are secured

to a urethral catheter. Pneumoperitoneum is established. Laparoscopic or robotic enterocystoplasty is performed using three to five trocars depending on the surgeon's experience and preference. The bladder is fully mobilized by incising the peritoneum medial to the obliterated umbilical ligament bilaterally, and the urachus is divided to "drop" the bladder posteriorly and enter the space of Retzius. An appropriate 15- to 20-cm segment of bowel is chosen taking care to ensure an adequate vascular pedicle and that the segment will reach to the bladder neck. The bowel work can be completed via a purely laparoscopic approach ([Meng et al, 2002](#)) or extracorporeally by extending the length of the umbilical incision ([Gill et al, 2000](#)) as described subsequently. In either approach, the segment is harvested using an Endo GIA stapler. The mesentery can be divided with additional reloads of the Endo GIA or with a 10-mm LigaSure device. Bowel continuity is reestablished with a side-to-side anastomosis using the Endo GIA device. The anastomosis is completed using a TA stapler (Covidien) if performed extracorporeally and with a series of Lembert sutures if performed using intracorporeal suturing ([Fig. 96-12](#)). The mesenteric window, or "trap," is closed to prevent internal herniation.

The bowel segment is irrigated copiously, the staple lines are excised on each end, and the segment is then opened along the antimesenteric border. During ileal augmentation, the sides of the bowel segment are approximated to form a U-shaped segment with running 2-0 polyglactin 910 suture. At this time, the bladder is filled with saline and bivalved at the midsagittal line. The segment is brought down to the pelvis without tension or torsion of the mesenteric pedicle. With the bowel segment oriented so that the apex of the U is positioned anteriorly at the bladder neck, the patch is sutured to the bladder in a running continuous fashion with 2-0 polyglactin 910 suture, beginning posteriorly and ending anteriorly ([Gill et al, 2000](#); [Elliott et al, 2002](#); [Meng et al, 2002](#)). The integrity of the completed augmentation is confirmed by irrigating the bladder via the Foley catheter, and finally a pelvic drain is positioned. Laparoscopic and robotic ileocystoplasty and cecocoloplasty with creation of a catheterizable stoma also have been

Figure 96-12. Technique for enterocystoplasty. **A**, Four-port transperitoneal technique is employed including an umbilical port, one port at each lateral border of the rectus muscle at the level of the umbilicus, and a port in the iliac fossa at the level of the anterior superior iliac spine. **B**, The selected bowel segment (15 cm) is exteriorized through an extension of the umbilical port incision. Alternatively, the bowel work can be performed intracorporeally. The anteroposteriorly bivalved bladder is shown. **C**, Ileoileal reanastomosis is performed cephalad (anterior) to the isolated bowel segment, which is detubularized and cleaned. Proper orientation of the bowel mesentery must be maintained. **D**, Ileovesical anastomosis is performed in a circumferential manner with continuous, full-thickness, freehand laparoscopic suturing with 2-0 Vicryl suture on a CT-1 needle. The completed augmentation ileocystoplasty is shown in the inset. (Reprinted with permission from The Cleveland Clinic Foundation. From Gill IS, Rackley RR, Meraney AM, et al. Laparoscopic enterocystoplasty. *Urology* 2000;55:178.)

described (Gill et al, 2000; Gundeti et al, 2008). For patients with concomitant refractory constipation, the Malone antegrade continence enema procedure can be performed concurrently (Shadpour et al, 2005). As an alternative to vesicoplasty for select patients, appendicovesicostomy has been performed laparoscopically (Hsu and Shortliffe, 2004; Lorenzo et al, 2007) and with a robotic-assisted laparoscopic approach (Lendvay et al, 2008). More recently, LESS enterocystoplasty has been reported, but larger series are needed to validate the efficacy and safety of the approach (Desai et al, 2009).

Outcomes and Complications

Complications of laparoscopic and robotic bladder augmentation are similar to complications encountered during open surgery and include infection, metabolic derangements, stones, perforation, mucus production, and malignancy. Intracorporeal bowel segment irrigation and detubularization may increase the risk of infectious complications.

Docimo and colleagues (1995) performed the first pure laparoscopic gastrocystoplasty in a patient with a five-port technique. The procedure involved almost 11 hours of operating time and a 13-day hospitalization. A laparoscopic-assisted approach, in which the laparoscopic work was largely limited to bowel mobilization, followed (Hedican et al, 1999; Chung et al, 2004). Gill and colleagues (2000) reported the first laparoscopic ileocystoplasty,

sigmoidocystoplasty, and cecocoloplasty. Bowel harvest and anastomotic work was done extracorporeally with a four-port approach. In this small series of three patients, operative times of 5 to 8 hours and blood loss of 50 to 200 mL were reported. A rectus sheath hematoma was the only complication that occurred. The first purely laparoscopic ileocystoplasty in a human was reported in 2002 (Elliott et al, 2002; Meng et al, 2002). The patient underwent a 9-hour procedure and required a 13-day hospitalization secondary to prolonged ileus. The largest published series of minimally invasive cystoplasty comprises six patients who underwent pure laparoscopic ileocystoplasty and an antegrade continence enema procedure (Shadpour et al, 2005). Operative times were 5 to 8.5 hours, with a median hospitalization of 5 days. Complications included one ileal anastomotic leak that resolved conservatively and one appendiceal stomal stenosis requiring revision. With intermediate-term follow-up (13 to 16 months), all patients were continent of urine between catheterizations, and nearly all had perfect fecal continence. Purely intracorporeal robotic augmentation ileocystoplasty with and without Mitrofanoff appendicovesicostomy also has been described (Al-Othman et al, 2008; Gundeti et al, 2008). The technique is essentially identical to the laparoscopic approach, but it may facilitate the learning curve for intracorporeal suturing. Famakinwa and associates (2013) updated this series and reported their experience of 18 children who underwent robotic-assisted laparoscopic Mitrofanoff appendicovesicostomy. With a median follow-up of 24.2 months, results were quite promising. The appendix was

anastomosed to the posterior wall of the bladder intravesically when concomitant enterocystoplasty was performed. It was done extravesically on patients who did not require an enterocystoplasty. Results and complications were in line with standard open techniques with a median operative time of 494 minutes (Famakinwa et al, 2013).

In a continuing attempt to improve cosmesis and possibly other outcome measures, LESS enterocystoplasty has been reported (Noguera et al, 2009). This technique is an exact replication of the technique described by Gill and colleagues (2000) with extracorporeal bowel work. The operating time was 300 minutes, estimated blood loss was less than 100 mL, and there were no intraoperative or postoperative complications.

Conclusions

Small feasibility studies documented that bladder augmentation cystoplasty can be performed laparoscopically, robotically, and, more recently, with a LESS approach. The principles of open cystoplasty can be replicated by experienced laparoscopic and robotic surgeons, despite the technical rigors associated with bowel work and extensive reconstruction. Although cosmetic outcomes are likely improved, further study is necessary to determine what additional benefits these approaches may confer to this patient population.

KEY POINTS: ENTEROCYSTOPLASTY

- Small feasibility studies document that bladder augmentation cystoplasty can be performed laparoscopically, robotically, and more recently with a LESS approach.
- The principles of open cystoplasty can be replicated by experienced laparoscopic and robotic surgeons, despite the technical rigors associated with bowel work and extensive reconstruction.
- Although cosmetic outcomes are likely improved, further study is necessary to determine what additional benefits these approaches may confer to this patient population.

VESICOVAGINAL AND URETEROVAGINAL FISTULA

Vesicovaginal fistula (VVF) is a distressing condition that often leads to significant psychological and medical morbidity. In the underdeveloped world, birth trauma is the most common etiology of VVF. Prolonged, obstructed labor leads to bladder ischemia and subsequent VVF formation (Miller and Webster, 2001). In developed nations, urogynecologic surgery is the most common cause of VVF, particularly as a complication of abdominal hysterectomy. VVF is estimated to occur after 1 in 1800 abdominal hysterectomies (Miller and Webster, 2001). Less common etiologies of VVF include trauma, foreign body erosion, pelvic irradiation, and other urogynecologic operations (Miller and Webster, 2001). Ureterovaginal fistulae (UVF) are also typically the result of ureteral injury during urogynecologic surgery, most often hysterectomy.

Evaluation and Surgical Indications

Patients with VVF/UVF after hysterectomy classically present with continuous urinary incontinence 10 to 14 days after surgery (Miller and Webster, 2001). A complete evaluation of upper and lower tract is necessary to identify the source of leakage as a VVF, urethrovaginal fistula, or UVF. Vesicouterine fistulae also can occur. All patients should undergo a thorough pelvic examination, cystoscopy, and vaginoscopy. A “double dye” tampon test with oral phenazopyridine and intravesical methylene blue is a useful office-based test. Appropriate imaging includes cystography and IVU to identify VVF and UVF, respectively. Retrograde ureterography is indicated if IVU is inconclusive for ureteral fistula (Miller and Webster, 2001).

Conservative management of VVF includes bladder drainage with a Foley catheter and/or endoscopic fulguration; however, success rates are low (7% to 12.5%) (Sotelo et al, 2005). Most fistulae ultimately require surgical repair, which can be done with an abdominal, vaginal, or combined approach. Controversy exists regarding the ideal approach for fistula repair, and surgeon preference and experience most often dictate the approach (Miller and Webster, 2001). It has been argued that large fistulae, fistulae in close proximity to the ureteral orifices, and recurrent fistulae after failed transvaginal repair are particularly well suited for an abdominal approach (Hemal et al, 2008). Similarly, controversy exists over the ideal timing of fistula repair. Although traditional management has favored delayed intervention, the literature supports early repair in select cases (Blandy et al, 1991; Blaivas et al, 1995; Langkilde et al, 1999; Miller and Webster, 2001).

Technique

Transabdominal VVF and UVF repair has been demonstrated to be feasible and effective using a pure laparoscopic or robotic-assisted laparoscopic approach. Core principles of open surgical fistula repair can and must be followed via minimally invasive approaches, including (1) wide exposure and complete excision of the fistulous tract; (2) optimal tissue health (adequate vascularity, freedom from infection, inflammation, and malignancy); (3) a tension-free, watertight, multilayered closure with nonoverlapping suture lines; (4) interposition of omentum, a peritoneal or bladder flap, or sigmoid epiploicae in between the bladder and vaginal suture lines; and (5) adequate postoperative bladder drainage (Sotelo et al, 2005; Wong et al, 2006).

After induction of anesthesia, cystoscopy is performed, and bilateral ureteral catheters are placed for ureteral identification and protection. To aid in identification and dissection of the fistulous tract, an additional ureteral catheter is passed from the bladder through the fistula and out the vaginal introitus. A Foley catheter can be used in lieu of a catheter for a large fistula. A sponge stick is placed in the vaginal vault to manipulate the vagina.

Pneumoperitoneum is established, and four or five trocars are placed, similar to bladder diverticulectomy (see Fig. 96-3). Two or three robotic arms can be employed, depending on the surgeon's preference. A transperitoneal approach is commonly employed. The patient is placed in the steep Trendelenburg position, and the robot is docked if a robotic-assisted approach is used. Cystoscopic illumination of the bladder allows for ready identification of the fistula location. Replicating the open technique described by O'Connor (1980), a vertical cystotomy incision is made from the dome to the fistula (Chibber et al, 2005). Sotelo and colleagues (2005) described a limited cystotomy in the vicinity of the fistulous tract to limit bladder dissection. Using this approach, dissection of the prevesical space and extensive bivalving of the bladder is avoided. Dissection is continued posteriorly until the catheter in the fistulous tract is identified. Alternatively, direct dissection in the vesicovaginal space can be performed. To prevent loss of pneumoperitoneum, a clamped Foley catheter with an inflated balloon and moist sponge pack can be placed in the bladder and vagina, respectively. The vesicovaginal space is dissected to separate the bladder from the vagina. The fistulous tract is excised completely, ensuring viable edges of bladder and vagina (Fig. 96-13).

The surgeon must remain cognizant of the ureteral orifices at all times to avoid injury. The bladder is closed vertically using 2-0 or 3-0 polyglactin 910 suture in two layers. The vagina is closed transversely to allow for nonoverlapping suture lines. Omental tissue can be interposed between the suture lines and anchored to the anterior vaginal wall with interrupted absorbable sutures (Sotelo et al, 2005). Alternatively, a peritoneal flap (Hemal et al, 2008; Gozen et al, 2009) or pericolic or mesenteric fat (Chibber et al, 2005) can be used for interposition. The bladder is filled with sterile saline to ensure a watertight closure. The ureteral catheters are removed. A Foley catheter in the bladder and closed suction pelvic drain are placed. The drain is removed within 24 to 48 hours. Cystography is performed 10 to 14 days after surgery, and the Foley catheter is removed.

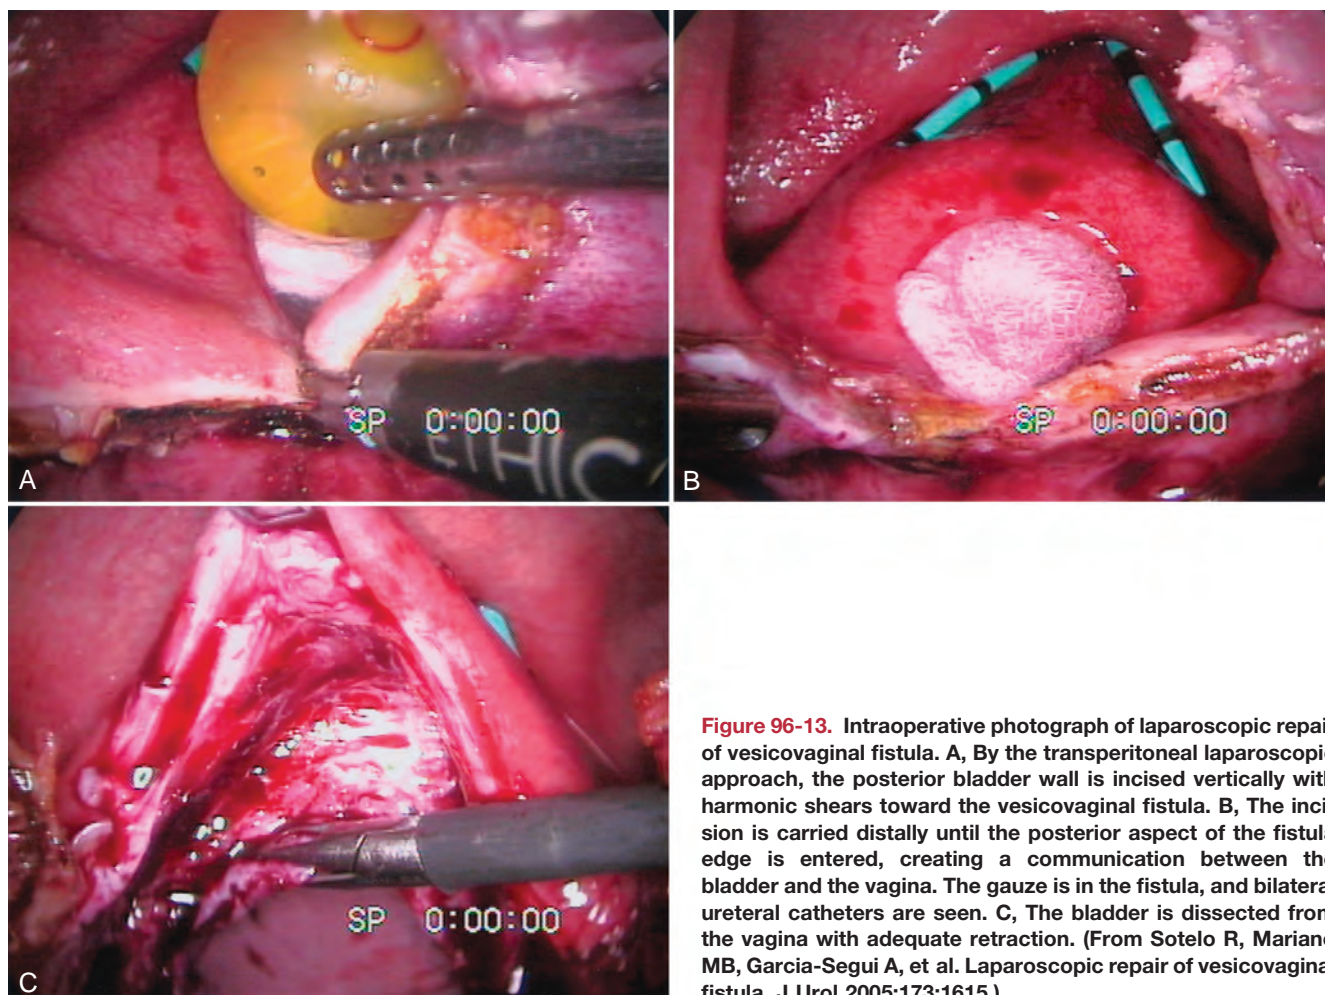

Figure 96-13. Intraoperative photograph of laparoscopic repair of vesicovaginal fistula. **A**, By the transperitoneal laparoscopic approach, the posterior bladder wall is incised vertically with harmonic shears toward the vesicovaginal fistula. **B**, The incision is carried distally until the posterior aspect of the fistula edge is entered, creating a communication between the bladder and the vagina. The gauze is in the fistula, and bilateral ureteral catheters are seen. **C**, The bladder is dissected from the vagina with adequate retraction. (From Sotelo R, Mariano MB, Garcia-Segui A, et al. Laparoscopic repair of vesicovaginal fistula. *J Urol* 2005;173:1615.)

Outcomes and Complications

Laparoscopic and robotic VVF repair were first performed in 1994 (Nezhat et al, 1994) and 2005 (Melamud et al, 2005), respectively. The reproducibility of laparoscopic VVF repair has been demonstrated with 49 patients reported in 12 published series (Sotelo et al, 2005; Gozen et al, 2009). In the largest reported series, Sotelo and colleagues (2005) reported success in 14 of 15 patients with a mean follow-up time of 26.2 months. Two complications occurred: one enterotomy and subsequent fistula and one epigastric arterial bleed requiring a return to the operating room. In a series of 11 patients with VVF and 1 patient with vesicouterine fistula, Das Mahapatra and Bhattacharyya (2007) had one failure with 12 to 36 months of follow-up. Chibber and colleagues (2005) reported on eight patients undergoing VVF or vesicouterine fistula repair with a 100% success rate at 3 to 40 months and no complications. Otsuka and colleagues (2008) successfully performed laparoscopic VVF on seven patients with no recurrences and two complications, including one urinary tract infection and an inferior limb compartment syndrome. Several authors also documented the feasibility and success of laparoscopic VVF for recurrent fistulae (Miklos et al, 1999; Nabi and Hemal, 2001; Otsuka et al, 2008).

Similarly, robotic-assisted laparoscopic VVF repair has been demonstrated as feasible in several series (Melamud et al, 2005; Sundaram et al, 2006; Schimpf et al, 2007; Sears et al, 2007; Hemal et al, 2008). With short-term follow-up, no failures and no complications have been reported to date. Successful laparoscopic and robotic-assisted laparoscopic ureterovaginal fistula repair also has

been reported (Ramalingam et al, 2005; Laungani et al, 2008). Similarly, laparoscopic and robotic rectourethral fistula repair and laparoscopic cervicovesical fistula repair have been reported (Hemal et al, 2001; Sotelo et al, 2007, 2008). Transvesical LESS VVF repair has been reported as well. The largest series in the literature included five patients (Abdel-Karim et al, 2011). In this series, VVF repair was performed using a TriPort (Olympus, Tokyo, Japan), bent instruments, and an EndoEYE camera (Olympus). An additional 5-mm port was added for triangulation and to aid with suturing. All repairs were done through an extravesical approach, but a cystostomy was made to excise the fistula tract, and an omental pedicle was interposed between the vagina and bladder at conclusion. The vaginal closure was performed with a one-layer closure using 3-0 polyglactin 910, and the bladder was closed in two layers using similar suture. Surgical times ranged from 170 to 240 minutes. All patients stayed in the hospital for 2 days. Mean follow-up was 8 months, and there have been no recurrences to date (Abdel-Karim et al, 2011).

Conclusions

Laparoscopic and robotic-assisted laparoscopic repair of VVF has been demonstrated to be reproducible and effective in small series. Larger series and randomized studies are necessary to determine what advantages may be conferred to patients compared with transabdominal and transvaginal approaches. In the future, LESS VVF repair may confer advantages of laparoscopy with optimal cosmetic outcomes.

KEY POINTS: VESICOVAGINAL AND URETEROVAGINAL FISTULA

- Larger series and randomized studies are necessary to determine what advantages may be conferred to patients compared with transabdominal and transvaginal approaches.
- In the future, LESS VVF repair may confer advantages of laparoscopy with optimal cosmetic outcomes.

URACHAL SURGERY AND PARTIAL CYSTECTOMY

The urachus is the embryologic remnant of the allantois and provides ligamentous support from the dome of the bladder to the umbilicus. Benign and malignant processes can affect the urachus. Benign conditions include urachal cysts and inflammatory and infectious processes. Urachal adenocarcinoma is rare and typically manifests as a tumor at the dome of the bladder, but it has been reported in the urachus alone without any bladder manifestations. Partial cystectomy can be performed for urachal adenocarcinoma and select cases of transitional cell carcinoma. Partial cystectomy is also indicated for other bladder pathology, including pheochromocytoma, lymphangioma, bladder sarcoma, and infiltrative endometriosis.

Evaluation and Surgical Indications

Most patients with urachal adenocarcinoma present with microscopic or gross hematuria. Occasionally, a mucinous adenocarcinoma may manifest with mucoid discharge or pyuria. Infected or inflamed urachal cysts may manifest with bloody discharge from the umbilicus or an indurated and fluctuant umbilicus. Diagnostic evaluation includes cystoscopy and CT. Cystoscopically, a lesion at the dome of the bladder is the hallmark finding. Imaging reveals a dome lesion in the bladder. Staging is critical to rule out lymphadenopathy or distant metastatic disease. For benign or infectious lesions of the urachus, CT may reveal a periumbilical cyst or abscess.

Treatment is indicated for symptomatic or infected urachal cysts. Although studies are limited, there is no clear evidence to suggest that urachal cysts will transform into urachal malignancies, and treatment should be limited to symptomatic patients. In the setting of inflammation or infection, patients should be treated with oral or intravenous antibiotics. Swab culture of the umbilicus and urine cultures should be sent before initiating antibiotics. Anti-inflammatory medications may be used for relief of symptoms. In the setting of a fluctuant umbilicus, local incision and drainage can be performed. If the infection resolves with complete relief of symptoms, no further intervention is required. In the setting of recurrent infected urachal cyst, surgical excision is indicated. The entire urachus should be excised including a small area on the dome of the bladder. If proper incision and drainage of any subcutaneous fluid has been performed, it is unnecessary to remove the umbilicus in the absence of malignancy.

Urachal carcinoma mandates a formal excision of the entire urachus, including a partial or radical cystectomy, depending on the extent of bladder involvement. Because these lesions often involve only the dome of the bladder, a partial cystectomy may be sufficient and has been demonstrated to provide equal oncologic efficacy (Herr et al, 2007). In this setting, the entire urachus is removed en bloc with the dome of the bladder inferiorly and the umbilicus superiorly. In addition, wide peritoneal wings are taken to ensure adequate margins. An extended pelvic lymphadenectomy is performed for adequate staging.

Patients with solitary transitional cell carcinomas at the bladder dome or within a bladder diverticulum are potential candidates for

partial cystectomy. Patients with multifocal disease are not candidates, mandating thorough cystoscopic evaluation with mapping bladder and prostatic urethral biopsies. Patients with bladder pheochromocytoma are managed medically to ensure medical optimization and avoidance of intraoperative hypertensive crises.

Technique***Patient Positioning and Port Site Placement***

Patients undergoing laparoscopic or robotic partial cystectomy are positioned in the dorsal lithotomy position. The patient is placed in the steep Trendelenburg position to allow the small bowel contents to migrate out of the pelvis for better visualization. Port configurations for laparoscopic and robotic partial cystectomy are similar to those used for diverticulectomy (see Fig. 96-3). When performing partial cystectomy for urachal carcinoma with removal of the umbilicus, the 12-mm camera port is inserted at least 5 cm above and 2 cm to the left of the umbilicus.

Cystoscopic Evaluation

When the patient is positioned and the ports are placed, the operating surgeon should begin with flexible or rigid cystoscopy. The robotic/laparoscopic intraperitoneal light is turned down so that the surgeon can see the illuminated bladder from inside the abdominal cavity; this allows the surgeon to delineate the involved area of the bladder from an intraperitoneal perspective and ensure adequate margins of resection (see Fig. 96-4). Electrocautery can be used to outline the area of resection on the outside of the bladder. When electrocautery is complete, the cystoscope is removed, and a Foley catheter is placed.

Surgical Technique

In contrast to conventional open surgery, when performing partial cystectomy for urachal cancer, the urachus is dissected out last. The laparoscopic/robotic surgeon should leave the bladder attached to the anterior abdominal wall during the initial dissection to maximize visualization and exposure. The bladder can be filled with approximately 200 to 300 mL of sterile water to define the anatomy better. Using an electrocautery, the bladder segment to be resected is scored, and dissection proceeds through all layers of the bladder with the exception of the bladder mucosa. Before dividing the bladder mucosa, the bladder should be emptied to avoid any spillage of bladder contents into the abdominal cavity. Before dividing the bladder mucosa, the entire urachus with wide peritoneal wings is dissected all the way to the level of the umbilicus. The urachus is divided at this level, and the umbilicus can be removed at the end of the case if necessary. When the entire urachus is dissected free, the bladder is opened, and the entire bladder lesion is excised circumferentially. The specimen is immediately placed in a 10- or 15-cm Endo Catch bag (Covidien). A frozen section analysis is performed on the bladder margin to ensure complete resection. If negative margins cannot be obtained, a radical cystoprostatectomy is performed. If margins are adequate, the bladder is closed in two layers using absorbable suture. A Foley catheter is left in place for 7 days and removed after negative cystography. An extended pelvic lymph node dissection is carried out as described subsequently. The specimen bag is retrieved at the time of umbilical resection through the resultant defect. All port sites are closed, and a pelvic drain is left in place for 24 hours. For partial cystectomy for transitional cell carcinoma or nonurachal pathology, the urachus can be taken down early in the dissection. After identification of the bladder pathology, a laparoscopic/robotic partial cystectomy can be performed via a combined extravesical and intravesical approach. In this technique, the bladder is opened anterior/superior to the pathology, allowing for an adequate margin, and the lateral and inferior borders are addressed for a circumferential dissection via an intravesical perspective (Fig. 96-14).

Figure 96-14. Robotic partial cystectomy for transitional cell carcinoma of the bladder. This muscle-invasive bladder tumor was addressed via a combined extravesical and intravesical approach. A, After illumination of the prior resection site, the bladder is entered superior to the tumor site. B, Once the bladder is entered, the dissection is completed by an intravesical approach circumferentially around the prior resection scar (star).

Outcomes and Complications

Multiple series have demonstrated the feasibility of laparoscopic and robotic partial cystectomy for a variety of bladder pathologies, including pheochromocytoma (Nayyar et al, 2010; Pandey et al, 2010; Kang et al, 2011), lymphangioma (Seyam et al, 2012), and endometriosis (Sener et al, 2006; Chammas et al, 2008). In several series on urachal and transitional cell carcinoma, hospital stay ranged from 2.5 to 4 days (Wadhwa et al, 2006; Colombo et al, 2008; Park et al, 2008); however, in our experience, patients can often be discharged on postoperative day 1 with the Foley catheter in place. With no recurrences at a mean follow-up of up to 28.5 months, preliminary data suggest these techniques to be oncologically sound with minimal complications reported (Wadhwa et al, 2006; Colombo et al, 2008; Park et al, 2008).

Conclusions

Laparoscopic/robotic partial cystectomy is technically feasible with limited morbidity. Available data are limited by short-term oncologic follow-up. With the growing popularity of robotic surgery, reported cohorts in the literature will likely grow, and confidence in the procedure will increase.

KEY POINTS: PARTIAL CYSTECTOMY

- Laparoscopic/robotic partial cystectomy is technically feasible.
- Morbidity is limited.
- The urologic literature is scant in reported series, and oncologic follow-up is short.
- This remains an untested technology in the treatment of urachal or transitional cell carcinoma.
- With the growing popularity of robotic surgery, reported cohorts in the literature will likely grow and confidence in the procedure will increase.

ROBOTIC RADICAL CYSTECTOMY

Given the significant complication rate associated with radical cystectomy, minimally invasive techniques have been employed in an attempt to reduce the morbidity of what has traditionally been one of the most invasive of urologic operations. Laparoscopic radical cystectomy (LRC) for the treatment of bladder cancer has proven feasible and reproducible. More recently, robotic-assisted radical cystectomy (RARC) has grown in popularity and has largely supplanted the laparoscopic approach. Ongoing research is helping to elucidate the degree of benefit offered by minimally invasive radical cystectomy and to demonstrate long-term oncologic outcomes.

Technique

Surgical Positioning and Port Placement

Operative setup is dictated in many cases by the specific characteristics of the operating room and the number of available assistants. We prefer to use the robotic fourth arm, positioned on the patient's right side two fingerbreadths above the right anterior superior iliac spine. The single bedside assistant is positioned on the patient's left. With this configuration, when the fourth arm grasper is employed, it can be used opposite the grasper that is typically in the surgeon's left hand. The result is two-handed grasping and manipulation. Operative setup for RARC when two bedside assistants are used is depicted in Figure 96-15. At least three monitors are needed in this setting. The scrub nurse should be positioned on the side of the assistant using the 15-mm port to facilitate exchange of clip applicators, sutures, and Endo Catch retrieval bags. The console surgeon must have easy access to the operative table to scrub into the procedure at a moment's notice.

The patient is placed in the dorsal lithotomy position using standard operative stirrups (Fig. 96-16). With the table flat, plastic sleds are used to tuck the patient's arms. All pressure points are protected using standard egg crate foam padding. The patient is secured to the operating table using a cross-shoulder harness made by four strips of egg crate foam padding. Each strip is 6 inches × 24 inches, and two strips are used on each side of the patient creating an "X" configuration across the patient's chest. The pads are secured to the operating table using cloth tape. Care must be taken not to

Figure 96-15. Operating room setup for robotic cystoprostatectomy. A, Surgeon; B, console; C, da Vinci system; D, scrub nurse; E and J, high-definition monitors; F, right assistant; G, left assistant; H, anesthesia. If using a robotic fourth arm, we prefer the solitary bedside assistant to be positioned on the patient's left, with a grasper employed via the fourth robotic arm positioned two fingerbreadths above the right anterior superior iliac spine. When the fourth arm grasper is employed, it can be used opposite the grasper typically in the surgeon's left hand to aim in two-handed grasping and manipulation.

Figure 96-17. Port site placement for robotic cystoprostatectomy with intracorporeal diversion. After insufflations, a 10- to 12-mm, bladed disposable trocar is placed superior to the umbilicus; the cephalad placement is important to reach the aortic bifurcation during extended lymphadenectomy and for intracorporeal bowel work. All remaining trocars are placed under direct vision. Left and right 8-mm robotic ports are placed 10 cm lateral to and 4 cm inferior to the camera port. A 12-mm trocar is placed for the bedside assistant port two fingerbreadths above the left anterior superior iliac spine; the fourth robotic arm is used with an 8-mm robotic trocar two fingerbreadths above the right anterior superior iliac spine. An additional 12-mm assistant trocar is placed midway between the camera port 8-mm robotic port on the ipsilateral side as the primary bedside assistant; this accommodates either a 10-mm LigaSure or a GIA stapling device to aid in transection of the bladder pedicles. Lastly, a 15-mm suprapubic trocar is used when performing intracorporeal urinary diversion, which aids in placement of the Endo GIA for side-to-side ileal anastomosis.

secure the lower portion of the pads below the costal margin because this may interfere with subsequent lateral port placement. Once the patient is secured to the table, the leg attachment is lowered, and the patient is placed in 30-degree steep Trendelenburg position. The anesthesia team places an orogastric tube to low wall suction for the duration of the case, and foam padding is placed over the patient's face to prevent injury from the camera, particularly when the 30-degree down lens is being used. A Foley catheter is placed on the operative field.

When performing intracorporeal urinary diversion, a 6- to 8-cm Pfannenstiel incision can be marked; a midline laparotomy incision is marked for specimen extraction and extracorporeal bowel work if preferred. For extended lymphadenectomy and the ability to visualize the aortic bifurcation adequately as well as maximal cranial dissection of the ureter, the camera trocar is best positioned approximately 25 cm from the pubic symphysis, or approximately 5 cm cephalad to the umbilicus. Initial access and insufflation of the abdominal cavity is performed using a Veress needle to 15 mm Hg. In obese patients, communication with the anesthesia team is imperative because pneumoperitoneum can result in unacceptably high inspiratory pressure necessitating a lower abdominal insufflation pressure. A six-trocar approach is employed (with an additional seventh trocar when performing intracorporeal diversion), as seen in [Figure 96-17](#).

Figure 96-18. A and B, Dissection of the ureter. Identification of the ureter, shown here on the patient's left side, begins with retraction of the sigmoid colon by the right bedside assistant (using a MicroFrance grasper) or robotic fourth arm (using a ProGrasp; Intuitive Surgical, Sunnyvale, CA). *A*, Pelvic sidewall and external iliac artery; *B*, hypogastric artery; *C*, ureter, retracted anteriorly by left robotic arm; *D*, bladder and ureteral hiatus; *E*, rectum; *F*, sigmoid colon; *G*, right robotic arm; *H*, suction-irrigator. The surgeon incises the posterior peritoneum overlying the external iliac artery, where the ureter is most easily identified. The ureter should not be directly grasped by the surgeon or the assistants, and effective ureteral retraction can be accomplished by placing the left robotic grasper beneath the ureter. The ureter is dissected proximally as high as possible to the level of the upper common iliac artery. Distal dissection is performed to the level of the ureteral hiatus.

Figure 96-19. A and B, Development of the anterior pedicle, shown here on the patient's left side, begins with identifying the avascular plane located between the pelvic sidewall and the bladder. *A*, Pelvic side wall; *B*, obturator nerve; *C*, internal iliac (hypogastric) artery; *D*, obturator artery; *E*, superior vesical artery; *F*, branch off of superior vesical artery; *G*, bladder; *H*, ureter; *I*, rectum; *J*, posterior pedicle to bladder.

Ureteral Identification and Transection

The technique for robotic cystectomy is described further on; laparoscopic cystectomy follows essentially the same procedure with differing instrumentation. Dissection is initiated by incising the avascular white line of Toldt on the patient's left; this allows the descending colon to be reflected medially exposing the retroperitoneal space beneath. This incision should be carried out as cranially as possible to allow for maximal left ureteral mobilization. The

ureter is identified and dissected proximally and distally. An identical dissection is performed on the right side (Fig. 96-18).

Division of the Anterior Pedicle

When each ureter is dissected as caudally as possible, the anterior pedicle to the bladder, including the superior vesical artery, is identified (Fig. 96-19). Identification is facilitated by developing the avascular plane between the external iliac vessels and the lateral aspect

of the bladder. At the most posterior aspect of this plane is the superior vesical artery. This vessel can be clipped and divided. In a non-nerve-sparing operation, the remaining anterior pedicle is divided using a 10-mm LigaSure device. In a nerve-sparing operation, surgical clips are employed to avoid the use of electrocautery near the neurovascular bundles. When the anterior pedicle is divided, this allows for identification of the ureteral hiatus into the bladder. At this point, each ureter is clipped and divided. The proximal clip has a long suture attached to it for identification at a later time in the case. At this point, both vasa deferentia can be divided as well.

Development of the Posterior Plane

After both ureters are divided, attention is paid to separating the bladder off of the rectum (Fig. 96-20). From left to right, the posterior peritoneal reflection between the bladder and the rectum is divided. The surgeon should be certain to get beneath the posterior leaflet of Denonvilliers fascia to ensure an adequate posterior margin. This plan of dissection is carried out as distally as possible, preferably to the level of the prostatic apex. This maneuver allows for identification of the posterior pedicles of the bladder. At this point, the bladder has not yet been released from its attachments on the anterior abdominal wall.

Division of the Posterior Bladder and Prostatic Pedicles

Using a 10-mm LigaSure device or reticulating laparoscopic stapler with 2.5-mm vascular staple loads, the bedside assistant divides the posterior pedicles of the bladder bilaterally (Fig. 96-21). This is carried out as distally as possible. In a nerve-sparing operation, clips and staples are used instead of thermal energy. Once the bladder pedicles are completely divided, the endopelvic fascia is divided on each side. This allows for identification of the prostatic pedicles, which are divided in a similar fashion (Fig. 96-22). This division should proceed as caudally as possible because the posterior plane will be difficult to visualize once the bladder is "dropped" posteriorly.

Dropping of the Bladder

When the pedicles are completely divided, the bladder can be released from its anterior abdominal wall attachments (Fig. 96-23). The urachus is first divided just below the level of the umbilicus.

Wide peritoneal wings are taken downward, and the median umbilical ligaments are divided. The space of Retzius is completely dissected. Any remaining endopelvic fascia is opened at this point. If a nonorthotopic urinary diversion is going to be performed, the puboprosthetic ligaments are divided. In an orthotopic urinary diversion, the puboprosthetic ligaments are preserved.

Division of Dorsal Vein Complex

A 0-0 polyglactin 910 suture on a CT-1 needle is passed underneath the dorsal vein complex, distal to the apex of the prostate (Fig. 96-24). Because urothelial cell carcinoma can involve the prostatic urethra, prostate-sparing cystectomy is not recommended, and the entire prostate is removed en bloc with the bladder. Once the DVC is secured, it is divided; this exposes the underlying urethra. The urethra is divided distal to the prostatic apex. The Foley catheter is lifted upward, and a Hem-o-lok clip is placed over it to prevent any urinary spillage into the operative field. The catheter is divided distal to the clip, leaving the balloon inflated acting as a ball valve to prevent spillage, and the assistant pulls the cut catheter in a cranial direction. The posterior urethra is divided, and any remaining attachments are released. The bladder, prostate, and seminal vesicles are placed into a 15-cm Endo Catch bag. At this point, an extended pelvic lymphadenectomy is performed.

Extended Pelvic Lymph Node Dissection

Pelvic lymphadenectomy is an essential component of radical cystectomy performed for malignancy (Fig. 96-25). Lymphadenectomy is essential for accurate staging, allowing the practitioner to counsel patients regarding prognosis and to make decisions regarding adjuvant treatment. The extent of lymphadenectomy has been correlated with improved oncologic outcomes, even in the setting of limited lymph node metastases. However, even when radical cystectomy is performed via an open approach, pelvic lymph node dissection is often limited or not performed at all. Over the last decade, there has been extensive literature documenting that an extended lymph node dissection can be performed via laparoscopic/robotic surgery. Several large series, including multicenter international consortia, have demonstrated high lymph node yields that demonstrate feasibility and reproducibility. With sufficient experience, an extended lymph node dissection can be performed robotically in approximately 45 to 60 minutes of operative time.

Figure 96-20. A and B, Once the anterior pedicles are divided, the posterior peritoneal reflection is incised separating the bladder and rectum in the midline. A, Bladder; B, rectum; C, left posterior pedicle; D, right robotic arm with monopolar scissors. The left assistant lifts the bladder anteriorly, and the right assistant retracts the posterior peritoneal edge. Using a combination of broad, sweeping motions and electrocautery with the monopolar scissors, one can develop the posterior plane between the bladder and the rectum beneath the posterior leaflet of Denonvilliers fascia. This dissection is carried as distally as possible and well beyond the vasa deferentia and seminal vesicles toward the prostatic apex.

Figure 96-21. A and B, Development of the plane between the bladder and the rectum reveals the posterior pedicle, shown here on the patient's left side. *A*, External iliac vein; *B*, obturator vein; *C*, bladder; *D*, rectum; *E*, sigmoid colon; *F*, posterior pedicle; *G*, superior vesical artery, cut; *H*, branch of superior vesical artery, cut; *I*, suction-irrigator. The posterior pedicle is located just distal to the previously divided anterior pedicle. Exposure of the left posterior pedicle is facilitated by the bedside assistant (or fourth robotic arm) providing superior and medial traction on the bladder, while the remaining assistant provides posterior retraction of the rectum. Division of the posterior pedicle is complete when the endopelvic fascia is encountered.

Figure 96-22. A and B, Adipose tissue overlying the endopelvic fascia, shown here on the patient's left side, is removed by the robotic instruments using sweeping motions. *A*, Pubic bone; *B*, pectineal line; *C*, bladder; *D*, posterior pedicle, cut; *E*, beginning of prostate pedicle; *F*, endopelvic fascia; *G*, right robotic arm. The endopelvic fascia is sharply incised using the robotic scissors. This exposes the prostate pedicles, which are secured and divided using the LigaSure device in a non-nerve-sparing operation or Hem-o-lok clips in a nerve-sparing procedure. To avoid injury to the rectum, the right assistant should retract the rectum posteriorly using either the suction or the grasper. It is important to carry this dissection as distally as possible because once the bladder is released from its anterior attachments, visualization of the posterior prostatic apex is quite limited.

We begin the dissection with a “split and roll” technique, beginning at the level of the external iliac artery. All lymph nodes are removed circumferentially around the artery. Dissection proceeds distally to Cooper ligament, with the lateral border being the genitofemoral nerve. The external iliac vein is identified, and all nodes are removed circumferentially around the vein, below the vein with the pelvic sidewall as the lateral border, and to the obturator nerve. All nodes around and below the obturator nerve and vessels are retrieved. The dissection continues proximally up

the common iliac artery, to the bifurcation of the aorta, and at least to the level of the inferior mesenteric artery. The hypogastric artery is identified and skeletonized. Presacral nodes are removed. The dissection continues to the contralateral side, where an equivalent dissection is performed, removing all lymph nodes from above the bifurcation down to the common, external, and internal iliac vessels distally to Cooper ligament. Lymph node packets are placed separately in entrapment bags to maximize lymph node counts.

Figure 96-23. A and B, Dropping the bladder from the anterior abdominal wall. Oncologic principles dictate removal of the urachus with the bladder en bloc with wide peritoneal wings. A, Anterior abdominal wall; B, urachus; C, medial umbilical ligaments; D, bladder; E, right robotic arm. The importance of placing the camera port several centimeters superior to the umbilicus at the beginning of the procedure is revealed. If the camera port is not placed superiorly enough, complete excision of the urachus is compromised as well as the proximal extent of the subsequent pelvic lymphadenectomy. The medial umbilical ligament on each side is grasped by the contralateral assistant and/or robotic fourth arm. Providing medial retraction, the monopolar scissors are used to incise the anterior peritoneum. The peritoneum is incised widely in an inferior direction until the pubic bone is exposed.

Figure 96-24. A and B, Transection of the dorsal vein complex. A, Pubic bone; B, puboprostic ligaments; C, prostate; D, bladder; E, left robotic arm. The puboprostic ligaments are preserved for orthotopic urinary diversion. For nonorthotopic diversion, the urethra is not preserved, and the puboprostic ligaments are divided for optimal distal dissection. A 0-0 polyglactin 910 suture is placed to secure the dorsal vein complex. In a non-nerve-sparing cystoprostatectomy, the dorsal vein complex can be divided with thermal modalities; in nerve-sparing procedures, electrocautery is avoided. The urethra is also divided without electrocautery for patients undergoing orthotopic neobladder construction. With superior traction on the bladder, the anterior half of the urethra is divided, and the Foley catheter is pulled into the patient. The catheter is secured with a large Hem-o-lok clip and divided, preventing possible tumor spillage. The left assistant provides superior retraction on the prostate and bladder by grasping the cut end of the Foley catheter. Remaining apical attachments are divided, and the bladder, prostate, and seminal vesicles are placed in a 15-mm Endo Catch bag (Covidien, Mansfield, MA).

Transposition of Left Ureter to Right Side

A separate plane is developed just anterior to the great vessels underneath the sigmoid colon (Figs. 96-26 and 96-27). A grasping instrument is placed from the right side under the sigmoid

mesentery to the left side. The suture on the end of the left ureter is grasped, and the left ureter is brought under the sigmoid colon to the right side. At this point, the extirpative portion of the operation is complete, and the surgeon proceeds to intracorporeal or extracorporeal urinary diversion and specimen extraction.

Figure 96-25. Extended lymphadenectomy. Borders of the dissection include inferior mesenteric artery/aortic bifurcation proximally, Cooper ligament inferiorly, genitofemoral nerve laterally, and sacral promontory medially. All presacral, hypogastric, external iliac, obturator, and common iliac lymph node packets are removed en bloc. A, After split and roll over the left common and external iliac artery (green arrow) and vein (yellow arrow), the lymph node packet is medialized and clipped distally at the level of Cooper ligament. B, All lymph node tissue is excised circumferentially around the common and external iliac arterial (green arrow) and venous (yellow arrow) systems. C, Nodes above and below the obturator nerve (yellow arrow) are removed. D, The presacral node packet (green arrow) is removed, and the sacrum is visualized (star). E, The right common iliac artery is medialized, with all nodes between the artery (green arrow) and vein (yellow arrow) removed, with the lateral border visualized (genitofemoral nerve) (black arrow). The sacrum is indicated by the star. F, Dissection is completed above the inferior mesenteric artery (green arrow).

Urinary Diversion. Urinary diversion is performed via an extracorporeal or a completely intracorporeal approach. Conventional options for diversion, including ileal conduit, continent cutaneous diversion, or orthotopic neobladder, can be performed using either approach, as described in a separate chapter. For extracorporeal diversion, a midline infraumbilical vertical incision is typically used, through which the specimens are extracted. When performing

intracorporeal diversion, a vertical or horizontal extraction incision (6 to 8 cm) is used (Fig. 96-28).

Female Robotic Cystectomy

Radical cystectomy in a female patient can be performed using laparoscopic and robotic approaches. Typically, this procedure involves

Figure 96-26. A and B, Transposition of the left ureter under the sigmoid colon. The left assistant places the suction-irrigator device through the left 5-mm port. With the right assistant retracting the sigmoid colon with a grasper, the surgeon defines a plane posterior to the sigmoid mesentery and superior to the aortic bifurcation just anterior to the great vessels. The suction device is passed from left to right along this plane. Further dissection is often necessary on the right side of the sigmoid mesentery to identify the tip of the suction device. A, Sigmoid colon; B, suction-irrigator, passed posterior to the sigmoid mesentery from the patient's left to right side; C, right robotic arm, elevating sigmoid colon. The right assistant passes a laparoscopic Maryland dissector through the 5-mm to 15-mm port, and the tips of the Maryland dissector are placed firmly into the suction device. The right assistant directs the instrument toward the patient's left side such that the tips of the Maryland dissector can be found posterior to the sigmoid mesentery on the patient's left side. The 0-0 tie attached to the left ureter is placed in the Maryland grasper, and the left ureter is brought behind the sigmoid mesentery to the patient's right side.

Figure 96-27. A and B, Completed transposition of the left ureter. A, Sigmoid colon; B, left ureter, passed posterior to the sigmoid mesentery and delivered to the patient's right side; C, Hem-o-lok clip with 0-Vicryl tie attached to the cut end of the left ureter; D, right robotic arm.

concomitant hysterectomy, bilateral salpingo-oophorectomy, and resection of the anterior vaginal wall. In appropriately selected patients, the gynecologic organs and vaginal wall can be spared.

Technique. After ureteral mobilization, the superior and inferior vesical arteries and the uterine and ovarian vessels are ligated. The round ligaments are transected, and the uterus, fallopian tubes, and ovaries are sutured to the obliterated umbilical ligaments to facilitate visualization of the posterior dissection. The peritoneum is incised in the pouch of Douglas. With the aid of a sponge stick in the vagina, the fundus is opened at the posterior fornix, just below

the level of the insertion of the cervix. The dissection proceeds distally to the level of the bladder neck. After identification of the bladder neck, the specimen is transected and excised approximately 0.5 cm distal to the bladder neck. The vaginal wall is closed either longitudinally or transversely with absorbable suture. In appropriately selected patients, the gynecologic organs and anterior vaginal wall can be spared (Fig. 96-29). After ureteral mobilization and transection, the peritoneum is incised in the uterovesical pouch. Dissection begins in the plane between the posterior bladder wall and anterior vaginal wall and continues distally to the level of the

Figure 96-28. Cosmetic results after robotic cystectomy and diversion. A, Robotic cystectomy with intracorporeal ileal conduit and 8-cm Pfannenstiel extraction incision. B, Robotic cystectomy with intracorporeal neobladder formation using 6-cm vertical extraction incision.

Figure 96-29. Organ-sparing female robotic radical cystectomy. The peritoneum is incised in the uterovesical pouch (A). Dissection begins in the plane between the posterior bladder wall and anterior vaginal wall and continues distally to the level of the bladder neck (B). The bladder neck is dissected circumferentially and transected (C). The urethral anastomosis is completed in this example of intracorporeal orthotopic neobladder construction (D).

bladder neck. The bladder neck is dissected circumferentially and transected, and the specimen is immediately placed in an entrapment sac (Table 96-1).

Outcomes and Complications

Robotic radical cystectomy is a challenging procedure that requires significant robotic surgical skills. The learning curve has been described by several groups, including the International Robotic Cystectomy Consortium (IRCC). The IRCC analysis suggested that after approximately 20 patients, it is possible to reach an acceptable operative time, and 30 cases were required to reach lymph node yields greater than 20 (Hayn et al, 2010a, 2010b). The same group explored the impact of prior robotic prostatectomy experience on RARC outcomes, demonstrating that previous prostatectomy case volume may improve operative time, blood loss, and lymph node yield at RARC; however, it did not appear to affect positive surgical margin rates.

Perioperative outcomes after LRC and RARC have been well characterized and compared with open surgical techniques. Retrospective comparative studies demonstrated that RARC is associated with reduced estimated blood loss and transfusion rates and shorter hospitalization, but longer operative times compared with open surgery (Wang et al, 2008; Kader et al, 2013). Randomized prospective trials demonstrated that RARC was associated with decreased estimated blood loss compared with open cystectomy and “trended” toward a decreased rate of excessive length of stay and fewer transfusions, with no difference in operative times (Parekh et al, 2013). In another randomized prospective trial, RARC was associated with reduced estimated blood loss, time to flatus and bowel movement, and in-hospital anesthesia, but longer operative times compared with open surgery (Nix et al, 2010).

Data regarding oncologic outcomes associated with LRC and RARC continue to accumulate. In an analysis of 513 patients, the IRCC demonstrated an overall positive margin rate of 6.8%, ranging from 1.5% for pT2 or less, to 8.8% for pT3, and to 39% for pT4 disease (Hellenthal et al, 2010). When comparing RARC with open cystectomy, retrospective series demonstrated no differences in pathologic outcomes such as lymph node yields or positive margin rates (Kader et al, 2013). Similarly, small randomized prospective trials demonstrated no differences in positive surgical margin rates or lymph node yields (Nix et al, 2010; Parekh et al, 2013). Additional studies have documented the feasibility of robotic extended node dissection and its equivalency to open surgery (Abaza et al, 2012; Desai et al, 2012). It has been demonstrated that high-volume institutions and high-volume surgeons are more likely to perform extended robotic node dissection, with higher node counts (Marshall et al, 2013). Few studies have documented long-term follow-up data, given the relative infancy of LRC/RARC compared with open surgery. For example, in a small set of patients with more than 5 years of follow-up, patients undergoing RARC experienced an overall survival of 64%, disease-specific survival of 75%, and disease-free survival of 50%, results that are comparable to open series (Khan et al, 2013). A series of 121 patients who underwent LRC or RARC provides the longest follow-up data available to date, with a median follow-up of 5.5 years. In this study, the actuarial overall survival, cancer-specific survival, and recurrence-free survival were 55%, 73%, and 71% at 3 years; 48%, 71%, and 65% at 5 years; and 35%, 63%, and 54% at 10 years (Snow-Lisy et al, 2014).

Complication rates associated with RARC have been reported and are generally comparable to open series. Within a large multi-institutional study of 939 patients (IRCC) with greater than 90 days of follow-up, 41% and 48% of patients experienced a complication within 30 and 90 days of surgery, respectively (Johar et al, 2013). Serious complications (high grade 3 to 5) occurred in 19% of patients. Gastrointestinal, infectious, and genitourinary complications were most common. Receipt of blood transfusion was associated with high-grade complications. Mortality was 1.3% at 30 days and 4.2% at 90 days. With standardized reporting, complication rates have been reported to be 80%, with 35% of these being major complications within 90 days (Yuh et al, 2012). In this series of

241 patients, the most common complications were infectious, gastrointestinal, and procedural complications. Several factors were associated with major complications, including comorbidity, preoperative hematocrit, and orthotopic diversion.

Retrospective and prospective randomized studies have compared complication rates between RARC and open cystectomy. In a retrospective study of 100 open versus 100 robotic cystectomies, the overall and major complication rates were lower for robotic versus open surgery (35% vs. 57% and 10% vs. 22%, respectively) (Kader et al, 2013). In a U.S. Nationwide Inpatient Sample comparing 1444 open with 224 robotic cystectomies, patients undergoing RARC experienced fewer inpatient complications (49.1% and 63.8%, $P = .035$) and fewer deaths (0% and 2.5%, $P < .001$) (Yu et al, 2012). In a randomized prospective trial of 41 patients, there was no significant difference in overall complication rates (Nix et al, 2010). Similarly, in the only other randomized trial to date, no difference was seen in the rate of complications of grade 2 or higher (Parekh et al, 2013).

The issue of cost-effectiveness also has been explored, comparing minimally invasive cystectomy with the open approach. Smith and colleagues (2010) demonstrated that robotic cystectomy is associated with a higher financial cost than open surgery. This higher cost was corroborated by Yu and colleagues (2012) comparing 1444 open and 224 robotic radical cystectomies. However, other authors have demonstrated that robotic cystectomy can be cost-effective compared with open surgery, particularly for ileal conduit reconstruction, where shorter length of stay and reduced complications can drive down comparative cost of the robotic approach (Lee et al, 2011a, 2011b).

Conclusions

Minimally invasive surgical techniques for radical cystectomy represent an evolving field in urology. Surrogates of oncologic efficacy and emerging long-term data suggest oncologic equivalency. Although studies suggest some perioperative benefits, at the expense of longer operating room times, further study is needed to elucidate exact benefits.

KEY POINTS: ROBOTIC RADICAL CYSTECTOMY

- Robotic-assisted radical cystectomy represents an evolving field in urology.
- It is certainly one tool that can be used in the treatment of invasive bladder cancer.
- Morbidity is limited, operative time is comparable, and long-term oncologic outcomes are awaited.

SIMPLE/SUPRATRIGONAL CYSTECTOMY

Evaluation and Surgical Indications

Nonradical cystectomy, also known as simple cystectomy or supratrigonal/prostate-sparing cystectomy, can be used as a last resort in many patients with unrelenting symptoms or persistent infections. Such circumstances may include intractable interstitial cystitis, radiation cystitis, hemorrhagic cystitis, intractable bleeding, postradiation fistulae, or postradiation urgency nonresponsive to medical/conservative therapy, among others. Surgical excision of the bladder, robotic or otherwise, should be considered only as a last-resort procedure after all other medical and more conservative therapies have failed. A formal discussion of urinary diversion options should be undertaken with the patient and family before surgery.

Technique

Robotic or laparoscopic simple cystectomy can be performed with a similar setup to radical cystectomy as described earlier. The ureters

are first isolated and transected at the level of the bladder. Posterior dissection is initiated by incising the posterior peritoneal reflection. The superior vesical artery and anterior pedicle to the bladder are divided. Posterior dissection is carried out to the level of the base of the prostate, just beyond the seminal vesicles. When the posterior dissection is complete, the bladder is dropped off of the anterior abdominal wall attachments. Once this is done, the anterior bladder is incised at the level just proximal to the prostate. The trigone is left intact. The posterior bladder wall is incised, and the bladder is placed in an Endo Catch bag for the remainder of the case. The trigone can serve as a point of attachment for a urethrovaginal anastomosis in the setting of an orthotopic urinary diversion. When a simple cystectomy is performed for postradiation fistulae, the prostatic fossa should be debrided of underlying necrotic tissue because this is a potential area of persistent postoperative infection and abscess formation. Consideration should be given to bringing in a vascular pedicle flap in this setting to allow for healthy tissue in growth and proper wound healing.

Outcomes and Complications

There have been no long-term studies of laparoscopic or robotic simple cystectomy. Most data are from case reports and personal reporting of single surgeon experiences. Complications are similar to complications reported in radical cystectomy series. Cases are highly selective, and each one must be considered on an individual basis.

TRANSVESICAL FOREIGN BODY AND STONE EXTRACTION

Indications

Transabdominal cystolithotomy is indicated in patients with very large and/or multiple bladder stones or when transurethral approaches are deemed inefficient (e.g., excessive stone burden, failed prior endoscopic treatment). This procedure is particularly indicated in patients with large prostates in whom minimally invasive suprapubic or retropubic prostatectomy is being performed concomitantly via laparoscopic or robotic approaches. In addition, foreign bodies within the bladder can be removed laparoscopically, via a transperitoneal or transvesical LESS approach, or robotically. Procedures for removal of foreign bodies have been described for objects including surgical materials and mesh (Maher and Feiner, 2011; Yoshizawa et al, 2011; Kim et al, 2012; Macedo et al, 2013; Roslan et al, 2013), migrated intrauterine devices, broken sewing needles (Lee et al, 2010), and electrical wires (Ko et al, 2010).

Technique

Various techniques can be employed for laparoscopic/robotic foreign body excision. A laparoscopic or robotic transperitoneal approach is the most straightforward technique. After standard abdominal insufflation, transperitoneal trocars are employed (Maher et al, 2011; Macedo et al, 2013). An anterior vesicotomy is performed, and the foreign body is visualized. Ureteral catheterization is performed if needed, and the foreign body is removed or excised. The bladder is closed with absorbable suture (Fig. 96-30).

The abdominal cavity can be avoided by using a transvesical approach, which can be performed with multiple trocars (Fig. 96-31) (Yoshizawa et al, 2011; Kim et al, 2012). After cystoscopy and saline instillation into the bladder, a 5-mm trocar is placed into the bladder under direct vision, the bladder is drained, and pneumovesicum is established at 8 to 12 mm Hg. Two additional trocars are placed, and foreign body excision is performed.

Transvesical excision of foreign bodies and/or mesh also can be performed via a transvesical single-site method (Fig. 96-32) (Ingber et al, 2009; Roslan et al, 2013). After cystoscopy and saline instillation, a single-site device is deployed, and the foreign body is identified and excised followed by bladder closure. To aid in retraction, a grasper can be placed transurethrally (Roslan et al, 2013).

Figure 96-30. Transperitoneal laparoscopic mesh excision. After establishment of pneumoperitoneum, transabdominal trocars are placed via traditional techniques. The bladder is opened and mesh, stones, or foreign bodies are removed. The bladder is closed in two layers with absorbable sutures. An intravesical mesh is shown with associated large bladder calculi.

Figure 96-31. Transvesical laparoscopic mesh excision. After cystoscopy, transvesical trocars are placed directly into the bladder. Pneumovesicum is established and maintained. Mesh or other foreign bodies are excised, and the bladder is closed with absorbable suture. (From Yoshizawa T, Yamaguchi K, Obinata D, et al. Laparoscopic transvesical removal of erosive mesh after transobturator tape procedure. *Int J Urol* 2011;18:861.)

Figure 96-32. Transvesical single-site mesh excision. After cystoscopy, the bladder is distended with saline. A single-site access port is placed directly in the bladder, and pneumovesicum is established. Transvesical single-site mesh excision is performed, and the bladder is closed. (From Ingber MS, Stein RJ, Rackley RR, et al. Single-port transvesical excision of foreign body in the bladder. *Urology* 2009; 74:1347.)

Renal Deterioration

Urinary Diversion

Metabolic and Neuromechanical Problems of Urinary Intestinal Diversion

Summary

Reconstructive urologic surgery frequently requires use of bowel for ureteral substitution, bladder augmentation, or bladder replacement. In rare cases, gastrointestinal segments may also function as urethral or vaginal substitutes. The stomach, jejunum, ileum, and colon all have a role in urinary tract reconstruction. Successful use of intestinal segments requires a thorough knowledge of their surgical anatomy. The surgeon must know the methods of preparing the intestine for an operation and the techniques for isolating segments of intestine and reconstituting continuity of the enteric tract. Crucial to success is an understanding of the technical procedures and potential complications of incorporating the intestine into the urinary tract. With this knowledge, reconstruction of the urinary tract may be performed with the proper segment of intestine in the least morbid way. This chapter reviews the technical aspects involved in the use of intestinal segments in urologic surgery that pertain to all types of reconstructive procedures and describes the important potential acute and long-term difficulties and complications of the use of intestinal segments.

SURGICAL ANATOMY

SELECTING THE SEGMENT OF INTESTINE

 Please see the Expert Consult website for this section.

BOWEL PREPARATION

It has been a long-held tenet of elective intestinal surgery that **bowel preparation is beneficial**. The bacterial population in the stomach is relatively low, but in the remaining segments of the bowel including the jejunum, ileum, and colon, there are high bacterial counts. Early studies suggested that bowel anastomoses in patients whose intestinal tract had not been prepared before surgery had increased wound infection rates, increased intraperitoneal abscesses, and an anastomotic dehiscence rate greater than in patients who received proper bowel preparation before surgery ([Irvin and Goligher, 1973](#); [Dion et al, 1980](#)). Other studies showed that mechanical preparation resulted in collapsed bowel at the time

of surgery, which was shown to reduce the incidence of anastomotic leaks ([Christensen and Kronborg, 1981](#)). Studies have recently begun to question the widely held belief that bowel preparation is mandatory. In meta-analyses of randomized clinical trials of anastomotic leakage during colon and rectal surgery, researchers found that there was no support for the conclusion that mechanical bowel preparation reduces anastomotic leak rates and other complications in elective open colon surgery ([Guenaga et al, 2011](#)). A randomized study in a small group of patients undergoing ileal loop diversion showed no difference in outcomes between the groups of patients who received bowel preparation and those who did not ([Hashad et al, 2012](#)).

In experimental animals, it has been shown that an anastomosis with vascular compromise at the anastomotic line, which would normally result in perforation, heals if the bowel has been properly prepared with antibiotics. Also, solid feces may place strain on the anastomosis in the early phase of healing and result in ischemia with subsequent perforation. **Complications that result from bacterial contamination are a major cause of morbidity and mortality in patients undergoing urologic procedures.** Infectious complications after radical cystectomy that are a direct result of fecal contamination may occur in 18% to 20% of patients who undergo radical cystectomy and include wound infections, peritonitis, intra-abdominal abscesses, wound dehiscence, anastomotic dehiscence, and systemic sepsis ([Bracken et al, 1981](#)). More recent series suggest that current management practices appear to have made a substantial improvement, with perioperative infectious complications of 7% ([Stein et al, 2004](#)). In another contemporary series of radical cystectomy with continent or ileal loop urinary diversion in 167 patients, there was an infection complication rate of 7.2% ([Mansson et al, 2003](#)). Another large series of 359 patients found infectious complications in 11.1% ([Berneking et al, 2013](#)).

There are two aspects to bowel preparation: **mechanical and antibiotic**. Both methods attempt to reduce the complication rate from intestinal surgery. **Mechanical preparation reduces the amount of feces, whereas antibiotic preparation reduces the bacterial count.** The bacterial flora in the bowel consists of aerobic organisms, the most common of which are *Escherichia coli* and *Enterococcus faecalis*, and anaerobic organisms, the most common of which are *Bacteroides* species and *Clostridium* species. The bacterial concentration ranges from 10 to 10⁵ organisms per gram of fecal content in the jejunum, 10⁵ to 10⁷ in the distal ileum, 10⁶ to 10⁸ in the ascending colon, and 10¹⁰ to 10¹² in the descending colon.

The segments of bowel urologists use most frequently are the ileum, colon, and rectum. The jejunum and stomach are also used, although less commonly, in reconstructive procedures. Successfully performing surgical mobilization of these structures and constructing them into their new role require a thorough knowledge of the surgical anatomy of the vascular supply and metabolic function of each portion of the intestinal tract.

Stomach

The stomach is a vascular organ that receives its blood supply primarily from the celiac trunk (Fig. 97-1). Three branches of the celiac axis give rise to the majority of the arterial supply of the stomach.

1. The **left gastric (coronary) artery** arises directly from the celiac axis and supplies the lesser curvature.
2. The **hepatic artery**, after arising from the celiac axis, **gives off the right gastric artery**, which also supplies the lesser curve of the stomach, and the **gastroduodenal artery**, which supplies the antrum and duodenum before giving off the **right gastroepiploic artery**.
3. The **splenic artery** originates from the celiac axis and gives off the **vasa brevia (short gastrics)**, which supply the fundus and cardia, and the **left gastroepiploic artery**.

The right gastroepiploic artery meets with the left gastroepiploic artery; thus both supply collateral flow to the greater curve of the stomach. By use of the gastroepiploic vessels, a pedicle of stomach may be mobilized as far as the pelvis. The pedicle may consist of the entire antrum pylori or a wedge of the fundus.

The blood supply for these segments is based on either the left or right gastroepiploic artery, depending on the portion of stomach used. On occasion, the left gastroepiploic artery is atretic at some point in its course and does not provide an adequate blood supply. Under these circumstances, the right gastroepiploic artery must be used. When a wedge of fundus is used, it should not include a significant portion of the antrum and should never extend to the pylorus or all the way to the lesser curve of the stomach. When the blood supply is based on the left gastroepiploic artery, the short gastric vessels that course from the gastroepiploic artery to the stomach are ligated along the greater curve proximal to the pedicle to the origin of the gastroepiploic artery. The omentum is left attached to the gastroepiploic vessels and helps secure and support them. It may be necessary for proper pedicle mobility to detach the omentum from the colon along the avascular plane located at the point of its attachment to the transverse colon. If an antrectomy is performed, a Billroth I anastomosis reconstitutes gastrointestinal continuity. The stomach has a thick seromuscular layer that can be easily separated from the mucosa should a submucosal ureteral reimplantation be necessary.

Figure 97-1. Arterial supply of the stomach.

Small Bowel

The small bowel is about 22 feet long; however, it may vary from 15 to 30 feet in length. Its largest diameter is in the duodenum; the lumen becomes smaller in the more distal portions, reaching its smallest diameter in the ileum, approximately 12 inches from the ileocecal valve. **About two fifths of the small bowel is jejunum, whereas the distal three fifths is ileum.** There is no definite demarcation between the two; however, each possesses several unique properties that allow the surgeon to distinguish one from the other intraoperatively. **The ileum, being more distal in location, has a smaller diameter. It has multiple arterial arcades, and the vessels in the arcades are smaller than those in the jejunum. The ileal mesentery is also thicker than the jejunal mesentery. In contrast, the jejunal diameter is larger, the arterial arcades are usually single, and the vessels composing them are larger in diameter.** The arcades anastomose one with another and give off straight vessels, which enter the bowel and form an anastomotic network within the bowel wall. **It has been shown experimentally that up to 15 cm of small bowel can survive laterally to a straight vessel.** Thus theoretically, the mesentery could be cleaned from the small bowel for a length of 15 cm without necrosis of the end. **In general, however, it is unwise to assume that more than 8 cm of small bowel will survive away from a straight vessel.** The arcades receive their blood from the superior mesenteric artery. When segments of jejunum or ileum are isolated, the mesentery should be transected in such a way that the isolated intestinal segment receives its blood supply from an arcade supplied by a palpable artery of substance that courses through the base of the mesenteric pedicle.

Two portions of the small bowel may lie within the confines of the pelvis and, as such, may be exposed to pelvic irradiation and pelvic disease: the last 2 inches of the terminal ileum, which is often fixed in the pelvis by ligamentous attachments, and the 5 feet of small bowel beginning approximately 6 feet from the ligament of Treitz, the mesentery of which is the longest of the entire small bowel. As such, this portion of the small bowel can descend into the pelvis. **In a postirradiated patient, one should try to avoid use of these two segments of the small intestine in any reconstructive procedure.**

Colon

The large bowel is divided into the cecum, ascending colon, transverse colon, left colon, sigmoid colon, and rectum. Portions of the large bowel are fixed or retroperitoneal, and other segments lie free within the peritoneal cavity. The cecum, on rare occasion, may lie free within the abdominal cavity and therefore may have great mobility. In general, however, it is fixed in the right lower quadrant. Two accessory peritoneal bands bind the cecum and distal ileum to the retroperitoneum and lateral abdominal wall. One band arises from the distal ileum, attaches to the cecum, and is fixed to the retroperitoneum. A second band arises from the cecum and fixes the cecum to the posterior abdominal wall laterally. The remainder of the ascending colon is fixed to the right posterior abdominal wall to the level of the hepatic flexure, at which point the hepatocolic ligament secures this portion of the colon to the liver. The transverse colon lies free within the abdominal cavity and is fixed in the left upper quadrant at the splenic flexure by the phrenocolic ligament. The transverse colon is attached to the stomach by the gastocolic omentum. The descending colon is fixed to the lateral abdominal wall; however, the sigmoid colon may or may not lie free within the abdominal cavity. The rectosigmoid colon's most cephalad portion is intraperitoneal, and at its distal, more caudad, portions it becomes retroperitoneal, and finally subperitoneal.

The colon receives its blood supply from the superior mesenteric artery, inferior mesenteric artery, and internal iliac arteries (Fig. 97-2). The major arteries supplying the colon and rectum include the ileocolic, right colic, middle colic, left colic, sigmoid, superior hemorrhoidal, middle hemorrhoidal, and inferior hemorrhoidal arteries. These arteries anastomose with one another to form the arc of Drummond and allow considerable leeway in

Figure 97-2. Arterial supply to the small bowel and colon.

mobilizing the colon. The middle colic artery arises from the first portion of the superior mesenteric artery and typically ascends the transverse mesocolon to the right of midline. The right colic artery usually arises just below the middle colic artery from the superior mesenteric artery and courses to the right colon. In some cases, the right colic may arise from the ileocolic artery or directly from the middle colic artery. If the right colic arises from the ileocolic artery, mobilization of a distal ascending colon segment is more likely to be brought easily into the deep pelvis. On occasion—particularly if the right colic artery originates from the middle colic artery—it is necessary to divide the right colic artery at its origin to mobilize the

distal portion of the ascending colon to the pelvis. The ileocolic artery is the terminal portion of the superior mesenteric artery and supplies the last 6 inches of ileum and ascending colon. The left colic artery arises from the inferior mesenteric artery, and then the inferior mesenteric artery gives off four to six sigmoid branches, the last of which becomes the superior hemorrhoidal artery. This anastomoses with the middle hemorrhoidal artery, a branch of the internal iliac artery, which in turn anastomoses with the inferior hemorrhoidal artery, the terminal branch of the internal pudendal artery. The middle sacral artery, which originates directly from the aorta, may supply the posterior aspect of the rectum.

Three weak points involving the vascular supply to the colon have been described. The **Sudeck critical point**, which is located between the junction of the **sigmoid and superior hemorrhoidal arteries**, was thought to be a particularly tenuous anastomotic area such that if the colon were transected in this region, the anastomosis would heal with difficulty because the blood supply might be compromised. Similarly, the **midpoints between the middle colic and right colic arteries and between the middle colic and left colic arteries also have somewhat tenuous anastomotic communications**. Although anastomoses in these areas usually heal well, provided the principles of proper technique are followed, it is usually wise to select an area for the anastomosis to one side of these points.

The ascending colon is mobilized first by transecting the cecal and distal ileal fibrous attachments to the lateral abdominal wall and retroperitoneum as described previously and then by detaching it from the lateral abdominal wall along the avascular line of Toldt. This is a bloodless plane, provided the colonic mesentery is not violated. The transverse colon is mobilized by dividing the gastocolic omentum (along the avascular plane of its attachment to the colon), the hepatocolic ligament (which may have some small vessels coursing through it), and the phrenocolic ligament. The descending colon is mobilized, much like the right colon, by incision of the avascular line of Toldt lateral to the colon. With these attachments taken down, there is considerable mobility of the colon. Further mobility is gained by isolating a pedicle of the intestinal segment on the basis of one of the major arterial vessels described earlier.

The stomach, jejunum, ileum, and colon have unique properties, each of which has special advantages and disadvantages. The selection of the proper intestinal segment should be based on the patient's condition, renal function, history of previous abdominal procedures, and type of diversion or substitution required. The stomach has been used as a replacement for bladder, for augmentation cystoplasty, as a conduit, and for continent diversions (Abdel-Azim and Abdel-Hakim, 2003; DeFoor et al, 2003; Bissada et al, 2004; Castellan et al, 2012). The advantages of the stomach over other intestinal segments for urinary intestinal diversion are that it is less permeable to urinary solutes, it has a net excretion of chloride and protons rather than a net absorption of them, and it produces less mucus. Urodynamically, it behaves as other intestinal segments do. When it is used in urinary reconstruction, electrolyte imbalance rarely ensues in patients with normal renal function, although a hypochloremic metabolic alkalosis has been described. The incidence of bacteriuria has been reported to be as low as 25%, much less than the 60% to 80% incidence reported for ileal and colon segments. However, more recent data suggest that there is no difference in bacteriuria among any of the segments. The urine, which usually has a pH of 6 to 7, does not typically result in an increased incidence of peristomal skin problems. Authors have also noted that in bladder augmentation patients, there is little difference in urinary pH between gastric and ileal augmentations. Serum gastrin levels are usually normal or minimally elevated, depending on what portion of the stomach is used and how much (Leong, 1978; Adams et al, 1988). Although exclusion of the antrum from the gastrointestinal tract has not resulted in elevated serum gastrin levels and an ulcer diathesis clinically (Lim et al, 1983), antral exclusion experimentally results in elevated circulating gastrin levels, which may cause major intestinal ulcerative problems in the postoperative period (Tiffany et al, 1986).

Rarely, severe ulcerative complications have occurred in cases in which stomach has been used for urinary reconstruction (Reinberg et al, 1992; Tainio et al, 2000). Long-term histamine (H_2) or proton-pump inhibition should be considered for these patients. When the antral portion of the stomach is used, reconstitution is generally by a Billroth I anastomosis. Complications with Billroth I gastroduodenostomy are well documented. The antrum should not be used if the fundus is available. Early complications of the use of portions of the stomach for reconstruction include gastric retention caused by atony of the stomach or edema of the anastomosis; hemorrhage, most commonly originating from the anastomotic site; hiccups secondary to gastric distention; pancreatitis as a consequence of intraoperative injury; and duodenal leakage. Delayed complications include dumping syndrome, steatorrhea, small stomach syndrome, increased intestinal transit time, bilious vomiting, afferent loop syndrome, hypoproteinemia, and megaloblastic or iron deficiency anemia. Postoperative bowel obstruction occurs with an incidence of 10% (2 of 21 patients) (Leong, 1978). Gastroduodenal and gastroureteral leaks have also been reported, occasionally resulting in a fatal outcome (Leong, 1978).

The use of stomach for urinary intestinal diversion may be considered when the use of other intestinal segments in a patient with a decreased amount of intestine would result in serious nutritional problems. One advantage of using stomach segments in the patient with severe abdominal adhesions is that the area of the stomach is, in general, adhesion free and easily mobilized. **Complications specific to the use of stomach include the hematuria-dysuria syndrome and severe metabolic alkalosis associated with respiratory distress in some patients (see the discussion of metabolic complications, later).**

The jejunum is usually not used for reconstruction of the urinary system because it may result in severe electrolyte imbalance. In general, diseases that would make the ileum inappropriate for use also make the jejunum inappropriate for use. Rarely, it is the only segment available. Under these circumstances, as distal a segment of jejunum as possible should be used to minimize the electrolyte problems.

The ileum and colon are used most often for urinary tract reconstruction and have been used in all types of reconstructive procedures. The ileum is mobile and of small diameter, has a constant blood supply, and serves well for ureteral replacement and the formation of conduits. **Loss of significant portions of the ileum results in nutritional problems because of lack of vitamin B_{12} absorption, diarrhea because of lack of bile salt reabsorption, and fat malabsorption.** On occasion, the mesenteric fat is excessive, making mobility and anastomosis difficult. Also, the mesentery may be so short that it is difficult to mobilize the ileum into the deep pelvis. **Postoperative bowel obstruction occurs in up to 10% of patients who have segments isolated from the ileum for urinary tract reconstruction (Varkarakis et al, 2006).** As many as half of the obstructions occur in the early postoperative period (Schwarz and Jeffs, 1975).

The colon requires mobilization from its fixed positions to give it the mobility necessary for use in urinary reconstruction. It has a larger diameter than the ileum and is usually easily mobilized into any area of the abdomen or pelvis. In patients who have received pelvic irradiation, portions of the right, transverse, and descending colon may be used confidently with the knowledge that they have not been exposed to the radiation therapy. Removal of segments of colon from the enteric tract results in fewer nutritional problems than does removal of segments of ileum, provided the ileocecal valve is not violated. Should the ileocecal valve be used, diarrhea, excessive bacterial colonization of the ileum with malabsorption, and fluid and bicarbonate loss may occur. **The incidence of postoperative bowel obstruction with colon is 4%, less than that occurring with ileum.** Both ileal and colon segments result in the same type of electrolyte imbalance with similar frequencies. **An antireflux ureterointestinal anastomosis by the submucosal tunnel technique is easier to perform with use of the colon.** In general, ileum and colon are comparable and have few differences, which does not argue strongly for the selection of one over the other except under special circumstances.

Mechanical Bowel Preparation

Mechanical bowel preparation reduces the total number of bacteria but not their concentration. Thus the same number of organisms is present per gram of fecal content (Nichols et al, 1972). Therefore spilling enteric contents during the procedure may be less likely with the mechanically prepared bowel because there is less of it to spill; however, once spilled, cubic centimeter for cubic centimeter, the inoculum is the same as if the bowel had not been prepared. Recent analysis has suggested, however, that there may in fact be an increase in bacterial contamination in patients who have undergone bowel preparation (Fa-Si-Oen et al, 2005).

Conventional bowel preparations commonly used in the past tended to exhaust the patient and exacerbate nutritional depletion because they typically required a 3-day preparation period of insufficient calorie intake (Table 97-1). The use of elemental diets has been advocated to clean the colon of feces while not compromising the nutritional status of the patient. Unfortunately, they have not proved useful because the elemental diets do not empty the colon of feces, and they do not reduce the bacterial flora (Arabi et al, 1978). In an attempt to reduce the time required for intestinal preparation and to obviate low-calorie intakes, whole-gut irrigation has been used. Originally, whole-gut irrigation was performed by placement of a nasogastric tube (NGT) into the stomach and infusion of 9 to 12 L of lactated Ringer solution or normal saline during a several-hour period. These fluids were subsequently replaced with 10% mannitol, which was equally successful in ridding the bowel of its fecal content; however, the mannitol served as a bacterial nutrient and thereby facilitated microbial growth (Hares and Alexander-Williams, 1982). These solutions have largely been replaced by a polyethylene glycol (PEG)–electrolyte solution. Whole-gut irrigation may be exhausting to the patient and may, in fact, result in a fluid gain, particularly when either saline or mannitol is used. Whole-gut irrigation is contraindicated in patients with an unstable cardiovascular system, patients with cirrhosis, patients with severe renal disease, patients with congestive heart failure, and those with an obstructed bowel. Whole-gut irrigation has been found to be no more effective than conventional preparations in reducing wound infections and septic complications (Christensen and Kronborg, 1981), even though there is a reduction of aerobic flora compared with the conventional preparations (van den Bogaard et al, 1981). The advantages of the whole-gut irrigation are that it gives the patient dietary freedom, there is a short preparation time, and it eliminates an enema. Its disadvantages are that it may result in the patient’s exhaustion, it is rather rigorous, and it does result on occasion in fluid overload.

The PEG-electrolyte lavage solutions (e.g., GoLYTELY or the more palatable NuLYTELY) are effective lavage agents in preparing the gut for elective colon and rectal surgery, as well as for urologic surgery in which bowel is used. For the adult, 20 to 30 mL/min or approximately 1 to 1.5 L/hr for 3 hours is given either orally or through a small-caliber NGT placed into the stomach. If it is taken by mouth, it is better tolerated if the solution is chilled. The administration of PEG lavage is stopped when the rectal effluent is clear and there is no particulate matter in it or when 4 L of fluid has been given. The septic complications with its use are approximately 4%. An inadequate preparation occurs in 5% of the patients using this

modality (Wolff et al, 1988). For children, even those younger than 1 year, PEG lavage may be used at a rate of 20 to 40 mL/kg/hr and given until the rectal effluent is clear and free of particulate matter (Tuggle et al, 1987). Metoclopramide, 10 mg in adults, is often given simultaneously to control nausea.

Oral cathartic bowel preparation is another acceptable strategy for reducing fecal burden before intestinal surgery. Oral solutions of magnesium citrate or sodium phosphate are both effective in cleansing the intestinal tract (Borden et al, 2010). The volume of fluid the patient must consume is substantially lower (148 mL MagCitra[®] and 45 mL NaPhosphate), and the preparations are typically well tolerated in healthy patients.

Bowel preparation can increase metabolic complications and cause electrolyte disturbances, which could affect surgical care. Caution must be exercised in elderly and debilitated patients receiving sodium phosphate preparation; the sodium phosphate preparation has been shown to cause significant derangements in potassium, calcium, and phosphorus levels in frail individuals (Beloosesky et al, 2003). Phosphate nephropathy has been recognized as a serious complication of oral sodium phosphate (OSP) bowel preparation (Markowitz et al, 2005). Caution should be used in prescribing OSP to patients with underlying renal insufficiency or being treated with nephrotoxic medications. In the United States, OSP was recently changed to prescription only by the U.S. Food and Drug Administration (FDA). OSP should rarely be used. The only study in postsurgical complications comparing sodium phosphate with PEG found no significant difference in complication rates (Oliveira et al, 1997). One study suggested that PEG is better tolerated by elderly patients and causes less disruption in potassium and sodium levels (Seinela et al, 2003). Oral electrolyte solution rehydration may prevent some of the complications of bowel preparation (Tjandra and Tagkalidis, 2004).

A number of studies have questioned the efficacy of mechanical bowel preparation. Some have suggested that a limited mechanical bowel preparation is all that is necessary; others have questioned even the need for a mechanical bowel preparation. In one study, 2 L of PEG plus metoclopramide was compared with the administration of 4 L of PEG solution. There was no difference in surgical complication rate or the extent to which the bowel was clean (Grundel et al, 1997). In another study, when 4 L of PEG was compared with 90 mL of sodium phosphate, there was no significant difference in surgical complication rate (Oliveira et al, 1997). Two meta-analyses have found that there is an increased anastomotic dehiscence rate with preoperative mechanical bowel preparation (Wille-Jørgensen et al, 2003; Bucher et al, 2005). PEG may be the agent responsible for the increased rate of complications, but other preparation strategies have not been adequately analyzed (Slim et al, 2004). A meta-analysis of randomized trials comparing mechanical bowel preparation with no bowel prep before elective colorectal surgery found no difference between the groups for anastomotic leakage, abdominal abscess, or wound sepsis (Slim et al, 2009). No study has adequately addressed the issue of the need for debulking of the intestine before laparoscopic approaches to intestinal surgery. It is extremely important to note that in these studies, the administration of intravenous antibiotics was crucial in keeping the complication rate low. Moreover, it is important to note that in these studies there was limited exposure of the

TABLE 97-1 Mechanical Bowel Preparation

PREOPERATIVE		CONVENTIONAL	POLYETHYLENE GLYCOL–ELECTROLYTE SOLUTIONS	
DAY	DIET	CATHARTIC	DIET	POLYETHYLENE GLYCOL
3	Low residue plus supplements	10 oz citrate of magnesia over 2 hr at 1 PM	Regular plus supplements	2–4 L (adults) or 25 mL/kg/hr × 2 hr (do not exceed 2 L) (children)
2	Low residue plus supplements		Low residue plus supplements

intestine because the patients underwent elective bowel resections, unlike urologic procedures in which long segments of the intestine are opened or interposed in a urinary tract that is normally free of fecal contents. No studies have carefully looked at the safety of omitting mechanical bowel preparation in urologic reconstructive surgery (Large et al, 2012).

Antibiotic Bowel Preparation

There has been considerable recent controversy as to whether the addition of oral antibiotics in elective colon and small bowel surgery reduces mortality and morbidity significantly. The long-held practice of mechanical and oral antibiotic bowel preparation dates to the 1970s. In one study, the septic complication rate was reduced from 68% in the control group to 8% in the antibiotic group (Washington et al, 1974). Most series, however, report a lesser incidence of reduction in wound infection, in general from 35% without antibiotics to 9% with their use (Clarke et al, 1977). Others have suggested that the mortality rate drops from 9% to 3% with the use of antibiotics (Baum et al, 1981). It is clear that the use of antibiotics protects vulnerable bowel in that it may allow the tenuous anastomosis to survive. Other studies, however, have shown that without the use of oral antibiotics in mechanically prepared bowel in elective surgery, the septic complication rate is comparable with that in those studies using antibiotics, and the rate of *Clostridium difficile* colitis was lower without oral antibiotics (Wren et al, 2005). In the presence of a bowel obstruction, however, oral antibiotics are of little value because they do little good in sterilizing the bowel. The disadvantages of antibiotics may include postoperative increase in the incidence of diarrhea; pseudomembranous enterocolitis; theoretically increased incidence of tumor implantation at the suture line that is not germane to urologic surgery; monilial overgrowth resulting in stomatitis, thrush, and diarrhea; and, with prolonged use, malabsorption of protein, carbohydrate, and fat. The antibiotics most commonly used for bowel preparation include kanamycin, which is the best single agent; neomycin and erythromycin base; and neomycin and metronidazole (Table 97-2). With an appropriate antibiotic preparation, enteric organisms are reduced to 10^2 per gram of feces (Nichols et al, 1972). A contemporary randomized trial of patients undergoing elective colonic surgery found the lowest fecal bacterial concentrations when patients had preoperative mechanical bowel preparation, oral neomycin, and supplemental "synbiotic" treatment (to provide benign flora to the intestine). No difference in clinical infections was seen between patients prepared with or without oral antibiotic bowel preparation (Reddy et al, 2007). A large series of 2475 patients from Michigan undergoing colon surgery showed lower infection (5.0% vs. 9.7%) and less *C. difficile* colitis (0.5% vs. 1.8%) with mechanical and oral antibiotic bowel preparation (Kim et al, 2014).

Perioperative intravenous antibiotics appear to be the most important means of preventing infectious complications of intestinal surgery. Systemic antibiotics must be given before the operative event if they are to be effective. Ideally, antibiotics should be given between 1 and 2 hours before the start of surgery (Classen et al, 1992). They appear to be most effective against the anaerobic flora and apparently reduce the complications caused by these

organisms (Dion et al, 1980). Perioperative systemic antibiotics, when added to the oral regimen, reduced the septic complication rate from 15% to 20% to half that rate in several series (Hares and Alexander-Williams, 1982; Gottrup et al, 1985). Other studies, however, have shown no effect of systemic cephalosporin, for example, in reducing septic complications (Wolff et al, 1988). If perioperative antibiotics are given, they should be effective against anaerobes because it is complications from these organisms against which perioperative antibiotics appear to be particularly effective. Third-generation cephalosporins have been advocated as an appropriate systemic antibiotic. Other recent studies support the use of both oral and systemic antibiotic prophylaxis before intestinal surgery (Kim et al, 2014). It is clear that preoperative antibiotics reduce postoperative complications. Most agree that preoperative intravenous antibiotics are important, and many advocate discontinuing the use of oral antibiotics because the incidence of *C. difficile* diarrhea may be increased and there appears to be no advantage, provided preoperative intravenous antibiotics are given within an hour of the operative event (Wren et al, 2005).

It is my preference to perform both a mechanical and an antibiotic bowel preparation. The patient is allowed a normal diet until 1 day preoperatively, at which time a clear liquid diet is begun and citrate of magnesia is taken as a cathartic. Oral antibiotic bowel preparation with neomycin and erythromycin base is also prescribed. On the day of surgery, the patient is given intravenous antibiotics 1 hour before the incision.

Diarrhea and Pseudomembranous Enterocolitis

Bowel preparations may result in diarrhea and pseudomembranous enterocolitis. Pseudomembranous enterocolitis is the more severe form of a spectrum of diarrhea. Clinically, this occurs after a bowel preparation in the postoperative period and is heralded by abdominal pain and diarrhea usually in the absence of fever or chills. As the symptoms and infection become more severe, systemic toxicity supervenes. These patients can develop a toxic megacolon, and if this occurs, the mortality may exceed 15% to 20%. Historically, pseudomembranous enterocolitis was thought to be caused by *Staphylococcus*, but there was, in fact, little evidence to support that organism as the causative agent. It is now clear that *C. difficile* plays a significant role in the majority of cases. *C. difficile* elaborates at least two toxins that cause diarrhea and enterocolitis. *C. difficile* does not invade the bowel, and it is not normally a significant inhabitant of the fecal flora. It is held in check by other bacteria that inhibit its growth. Thus antibiotics destroy the bacteria that inhibit the growth of *C. difficile* and thereby allow it to flourish. The toxin produces a diffuse inflammatory response with cream-colored plaque formation, erythema, and edema of the bowel wall. On microscopic examination, the villi appear to be intact and there is a polymorphonuclear leukocyte infiltrate of the submucosa (Bartlett, 2002).

As the disease progresses, large areas of mucosa may slough and areas of the bowel are denuded of their mucosa. The lesions may involve the colon, in which case it is called *pseudomembranous enterocolitis*, or the small bowel, in which case it is called *pseudomembranous enteritis*, or they may involve both. The diagnosis may be suspected from the symptoms or endoscopy and is confirmed by

TABLE 97-2 Antibiotic Bowel Preparation

PREOPERATIVE DAY	KANAMYCIN	NEOMYCIN PLUS ERYTHROMYCIN BASE	NEOMYCIN PLUS METRONIDAZOLE
3	1 g kanamycin orally every 1 hr × 4, then 4 times/day	—	—
2	1 g kanamycin orally 4 times/day	—	1 g neomycin 4 times/day plus 750 mg metronidazole 4 times/day
1	1 g kanamycin orally 4 times/day	1 g erythromycin base plus 1 g neomycin at 1 PM, 2 PM, and 11 PM	1 g neomycin 4 times/day plus 750 mg metronidazole 4 times/day

culture of the organism or identification of its toxin. Because culture takes a prolonged time, it is more expeditious and therefore clinically useful to confirm the diagnosis by identifying the toxin produced by *C. difficile*. Once the diagnosis has been made, treatment involves the administration of vancomycin or metronidazole and discontinuance of other antibiotics that the patient is receiving. Vancomycin or metronidazole is effective in most cases. Rarely, toxic megacolon supervenes, necessitating subtotal colectomy as a lifesaving procedure (Chang, 1985). Newer therapy with antibodies to the toxin hold promise in reducing the morbidity of the disease (Lowy et al, 2010).

INTESTINAL ANASTOMOSES

Regardless of the type of anastomosis or the methods used to perform it, certain fundamental principles must be observed to minimize morbidity and mortality from intestinal surgery. **In urologic procedures in which gut is used, the most common cause of mortality and morbidity within the immediate postoperative period relates to complications involving the bowel,** either with the enteroenterostomy or with the segment interposed in the urinary tract. Therefore it cannot be overemphasized that great care must be taken and proper techniques used in handling bowel in urologic procedures. Unfortunately, the portion of the procedure that involves mobilization of the intestine and reanastomosis often follows a rather lengthy extirpative endeavor and is performed when the surgical team is not fresh. Therefore the following principles should be so firmly ingrained in the surgeon that they are performed without the need to recall each one specifically.

The first principle of proper technique for intestinal anastomoses is adequate exposure. The intestine should be mobilized sufficiently that the anastomosis may be performed without struggling for exposure. If possible, it is preferable to mobilize the intestine sufficiently so that the anastomosis can be performed on the anterior abdominal wall. The area of the anastomosis should be walled off from the rest of the abdominal cavity with Mikulicz pads. This is important so that any inadvertent enteric spills are not distributed throughout the abdominal cavity. The mesentery must be cleared from the bowel segments to be anastomosed for a suitable distance (usually 0.5 cm) from the intestinal clamps or staple line at the severed ends so that good serosal apposition may be achieved without interposed mesentery. Sufficient serosa must be exposed so that the seromuscular sutures or staples can be placed directly in the serosa without traversing the mesentery.

The second principle of performing a proper anastomosis is to maintain a good blood supply to the severed ends of the bowel. The blood supply may be compromised by construction of an anastomosis under tension, excessive dissection or mobilization of the bowel, excessive use of the electrocautery, and tying of the sutures so tightly that the intervening tissue is strangulated. A cut margin of bowel that is pink and bleeds freely suggests that the blood supply has not been compromised; however, hemostasis must be ensured before beginning the anastomosis. The site of transection is selected at a point where the blood supply is adequate to both segments. The mesentery should be transilluminated so that the blood supply may be defined before transection of the bowel segment. In urologic surgery, the location of the transection is elective so that an area may be selected in which excellent arcades supply both sections of the transected segment. The area must be selected with an eye to how deep the mesenteric transection must be for proper segment mobility. After location of the appropriate area where the mesentery is to be transected, it is cleaned from the serosa, severed between mosquito clamps, and tied with 4-0 silk sutures. Alternatively, the mesentery may be transected with the LDS staple device (Covidien Surgical, Mansfield, MA), a bipolar cautery device, or ultrasonic shears.

The third principle involves prevention of local spillage of enteric contents. The best way of preventing spills is to operate on bowel properly prepared (i.e., devoid of feces and collapsed). Stripping of the enteric contents between the fingers both cephalad

and caudad from the proposed transection site and application of a noncrushing occlusive clamp across the bowel make a spill even less likely. The clamp should prevent enteric contents from exiting the cut ends of the bowel without interference with the mesenteric blood supply. After linen-shod clamps are applied and the area is walled off, Allen clamps are applied to the bowel and the bowel is transected between the Allen clamps. An anastomotic staple device may be used to transect the bowel at this point in place of Allen clamps (see later). Local spills and local sepsis have an adverse effect on the healing anastomosis, and it is for this reason that noncrushing occlusion clamps, in addition to an adequate bowel preparation, are advisable. If a spill does occur, it should be caught in the Mikulicz pads if the bowel has been properly walled off as described previously. The isolated segment that is to be used in the reconstructive procedure should be irrigated thoroughly with copious amounts of normal saline. The segment should be walled off. The irrigant is placed in one end of the segment and caught in a kidney basin as it exits the other end. This should be continued until the efflux is clear. This procedure prevents local spills during the ureterointestinal anastomosis and other aspects of reconstruction.

The fourth principle, germane to all intestinal anastomoses, is that there should be an accurate apposition of serosa to serosa of the two segments of bowel to be anastomosed. The anastomosis should be watertight and performed without tension. The bowel must be handled gently with the use of noncrushing forceps. The anastomotic line should be inverted and not everted. There is considerable controversy about this issue in that an everted anastomosis has been shown to heal with few complications. It is clear that when marginal conditions occur, an inverted anastomosis is more likely to remain intact than is the everted anastomosis.

The fifth principle is not to tie the sutures so tightly that the tissue is strangulated. Obviously, the sutures must bring the serosa of the two segments firmly together. Nonabsorbable sutures used for the anastomosis result in a stronger anastomotic line in the early healing phase compared with absorbable sutures, but the difference is minimal and probably not particularly significant.

The final principle involves realignment of the mesentery of the two segments of bowel to be joined. These should be parallel to each other; the surgeon should ensure that there is no twist on completion of the anastomosis.

Factors that significantly contribute to anastomotic breakdown include poor blood supply, local sepsis induced by fecal spillage, drains placed on an intra-abdominal anastomosis, and anastomosis performed in irradiated bowel. Poor blood supply and local sepsis cause ischemia. Drains placed on the anastomosis increase the likelihood of an anastomotic leak, and an anastomosis performed in irradiated bowel is more likely to result in an anastomotic failure than one performed in nonirradiated tissue. The importance of careful technique and adherence to these principles is emphasized by the fact that in one series of urinary intestinal diversion, 75% of the lethal complications that occurred in the postoperative period were related to the bowel. Eighty percent of these patients had received radiation before the intestinal surgery (Mansson et al, 1979). Prior radiation significantly increases the likelihood of serious complications after radical cystectomy (Eswara et al, 2012).

Types of Anastomoses

Intestinal anastomoses may be performed with use of sutures or staples. Properly performed, both have similar complication rates (Catena et al, 2004). In selected circumstances, however, one method may have advantages over the other. **Because there is a high rate of stones that form on surgical staples (Woodhouse and Robertson, 2004), absorbable suture should be used for intestinal segments that are exposed to urine (e.g., suturing intestine to renal pelvis or bladder, closing the proximal end of a conduit [Costello and Johnson, 1984], and forming an intestinal pouch for urine).**

Enteroenterostomy by a Two-Layer Suture Anastomosis

A 3-0 silk holding suture is placed on the mesenteric border just beneath the Allen clamps traversing both segments to be anastomosed, and a second suture is placed on the antimesenteric border similarly just beneath the Allen clamps (Fig. 97-3). It is important that the mesentery be cleaned sufficiently that these sutures can be placed in the serosa under direct vision. A row of silk sutures is placed 2 mm apart between the two holding sutures. This is accomplished by rotating the two Allen clamps away from each other, thus apposing the serosal surfaces. Sutures must traverse the muscularis but should not traverse the full thickness of the bowel. After all sutures have been placed, each is tied and the tails of all the sutures are cut, except those at each end; these are used as holding sutures. The Allen clamps are removed, and hemostasis is achieved, if necessary, with the light application of electrocautery. A 3-0 double-ended chromic intestinal suture is placed in the posterior suture line through all layers and tied to itself. Each end of the suture is then run in a locking fashion away from the midpoint until the mesenteric and antimesenteric borders are approached. As the lateral aspects of the bowel are approached, the suture is converted to a Connell suture (Fig. 97-4), which proceeds onto the anterior

Figure 97-3. Two-layer suture anastomosis. A, Two holding sutures of 3-0 silk have been placed at the mesenteric and antimesenteric border, and the posterior wall is approximated with seromuscular sutures of 3-0 silk. B, A 3-0 intestinal chromic suture is placed through the full thickness of the bowel posteriorly, tied to itself, and run to the lateral borders with a continuous locking suture. At the lateral borders, it is converted to a Connell suture. C, The Connell suture brings the anterior margins together, inverting the suture line. The anastomosis is completed by placement of horizontal mattress seromuscular sutures of 3-0 silk over the anterior suture line (not depicted).

Figure 97-4. Connell suture. The suture traverses the bowel from serosa to mucosa and then from mucosa to serosa on the same side of the anastomosis. The suture is then placed on the opposite side of the anastomosis “outside in–inside out.” The sequence is repeated until the two segments are approximated.

bowel wall. The sutures meet anteriorly in the midline and are tied together. The anterior serosa is then apposed with interrupted 3-0 silk sutures. The noncrushing occlusive clamps are removed, and the mesentery is closed with interrupted 3-0 silk sutures.

Patency of the anastomosis is ensured by palpating the anastomosis with the thumb and forefinger and feeling an annulus of tissue around the fingers. This anastomotic technique is used when the antrum pylorus is removed and intestinal continuity is restored by a Billroth I procedure. It is also the most secure of all the anastomoses and should be used when one is forced to do an anastomosis under less than ideal circumstances.

Enteroenterostomy by a Single-Layer Suture Anastomosis

The single-layer anastomosis for reapproximating bowel is an excellent technique with a low complication rate, that is, a 0.2% anastomotic leakage rate compared with an 8.4% anastomotic leakage rate for a stapled anastomosis in one large series (Leslie and Steele, 2003).

The mesenteries of the two segments of bowel to be anastomosed are aligned, and a 3-0 silk suture is passed through the seromuscular layers of both segments on the mesenteric side; a second suture is similarly placed on the antimesenteric side. The mesenteric suture is tied, and the antimesenteric suture is left untied. The Allen clamps are removed, and hemostasis is achieved with light electrocautery. The critical point of the anastomosis, where most leaks occur, is at the mesenteric border. Leaking usually occurs because the sutures are placed carelessly or the serosa has not been cleaned of mesentery sufficiently that the sutures can be placed through it under direct vision. Because this mesenteric border is the critical area, it is approached first. Two 3-0 silk sutures are placed through the full thickness of the bowel on either side of the mesenteric holding suture. These sutures are placed in such a way as to include more serosa than mucosa, thus causing inversion of the suture line (Fig. 97-5A). Some prefer to use a Gambee stitch at this point, which involves placing the suture through the full thickness of the bowel followed by traversing a small segment of mucosa of each segment of bowel before exiting through the full thickness of the bowel of the other segment (Fig. 97-5B). The two bowel sutures on the mesenteric border are tied, with care taken to invert the suture line, thus apposing serosa. Then 3-0 silk sutures are placed 2 mm apart, both on the anterior and posterior walls, inverting the suture line, thus apposing the serosa of the two bowel segments to each other. On approaching the antimesenteric holding suture, several sutures are placed before all are tied. A patent

Figure 97-5. A, When it is properly placed, the suture through the intestine should include more serosa than mucosa. B, The Gambee stitch. The suture is placed through the full thickness of the bowel, the mucosa is traversed, and then the mirror image procedure is performed on the segment to be anastomosed.

anastomosis is confirmed by feeling the annulus with the thumb and forefinger as described previously.

End-to-Side Ileocolic Sutured Anastomosis

The transected end of the colon is closed in the following manner (Fig. 97-6). A 3-0 silk suture is placed beneath the Allen clamp on the mesenteric border, and a second suture is placed on the antimesenteric border. These are tied. A 3-0 chromic suture is placed beneath the clamp in a horizontal mattress fashion. Beginning at the mesenteric border, it is tied to itself and the horizontal mattress suture is placed until the antimesenteric border is reached, at which point the suture is again tied to itself. The clamp is removed, and an over-and-over suture is performed with the same chromic suture throughout the full thickness of the bowel until returning to the point of origin (i.e., the mesenteric border is approached). At this point, the suture is again tied to itself. The suture line is buried by approximating the serosa on each side with interrupted 3-0 silk sutures placed 2 mm apart. Our preference is to close the end of the colon similarly to the way one closes the proximal end of a conduit. After a 3-0 silk suture is placed through the serosa on the antimesenteric and mesenteric sides, the clamp is removed and a 3-0 chromic suture is placed through all layers at the mesenteric and antimesenteric end. A Connell suture is used—the two chromic sutures meet in the middle and are tied together. Seromuscular sutures of 3-0 silk are placed to appose the serosal margins.

The mesenteries are aligned, and the ileal serosa is sutured with interrupted 3-0 silk sutures to the colonic serosa 2 mm below a taenia (Fig. 97-7). The taenia is incised the length of the diameter of the ileum adjacent to it. As described earlier for the two-layer anastomosis, a 3-0 double-ended intestinal chromic suture is placed through all layers of the colon and ileum in the midpoint of the posterior wall and run in a locking fashion laterally to either side of the incision in the taenia. At the most lateral border, the suture is converted to a Connell suture and the anterior wall is closed. Seromuscular sutures of 3-0 silk placed from ileum to colon bury the anterior suture line. The mesentery is reapproximated.

Ileocolonic End-to-End Sutured Anastomosis with Discrepant Bowel Sizes

A 3-0 silk suture is placed on the mesenteric border of the ileum and colon (Fig. 97-8). A second 3-0 silk suture is placed on the antimesenteric border of the colon immediately beneath the Allen clamp. The other end of the suture is placed on the antimesenteric border of the ileum at a distance proximal to the Allen clamp so that the serosal lengths between the two sutures of both ileal and colon segment are equal. Thus an equal amount of ileal serosa is applied to the length of colonic serosa bordering the severed end

of bowel. In the seromuscular layers of ileum and colon, 3-0 silk sutures are placed 2 mm apart, thus apposing the serosa of the ileum to the colon. The Allen clamps are removed. Hemostasis is achieved, and the antimesenteric border of the ileum is incised to the level of the most proximal suture in the ileum. Thus the bowel lumens are now of identical size. With a 3-0 chromic double-ended intestinal suture, the posterior row is run in a locking fashion, laterally converting to a Connell suture, and the anterior row is completed. Seromuscular sutures of 3-0 silk bury the anterior suture line.

Stapled Anastomoses

The theoretical benefits of a stapled anastomosis are that it provides for a better blood supply to the healing margin, there is

Figure 97-7. End-to-side anastomosis. A, The serosa of the ileum is sutured to the serosa of the colon 2 to 3 mm below a taenia. B, The taenia is opened for a distance sufficient to accommodate the diameter of the ileum. A 3-0 chromic suture is placed through all layers on the posterior wall, tied to itself, run in a locking fashion to both borders, and converted to a Connell suture laterally, thus completing the inversion anteriorly. C, The anterior margin of serosa is reapproximated with interrupted horizontal mattress sutures of 3-0 silk.

Figure 97-8. Anastomosis of discrepant-sized bowel. A seromuscular suture of 3-0 silk is placed adjacent to each end of the lumen on the mesenteric side. A second 3-0 silk seromuscular suture is placed adjacent to the lumen on the colon and on the antimesenteric border proximal to the cut end of the small bowel at a distance sufficient that when the antimesenteric border is incised, the lumens are the same size. Interrupted seromuscular sutures of 3-0 silk are then placed at 2-mm intervals between the two holding sutures. The small bowel is opened on its antimesenteric border until the opening in the small bowel is the same size as the opening in the colon. A 3-0 chromic suture is placed through all layers, tied to itself, and run laterally in a running locking fashion. At the borders, it is converted to a Connell suture, thus inverting the anterior margin. The anastomosis is completed with interrupted horizontal mattress 3-0 silk sutures that bring the seromuscular layers together anteriorly. This is similar to the closure depicted in Figure 97-3.

Figure 97-6. Closure of the proximal end of the intestine. A, A 3-0 chromic suture is tied to itself at the antimesenteric border and placed beyond the intestinal clamp in a horizontal mattress fashion until the mesenteric border is reached. The suture is then tied to itself at this point. B, The intestinal clamp is removed, and an over-and-over suture through the full thickness of the bowel returns the chromic suture to its point of origin, where it is again tied to itself. C, Interrupted horizontal mattress seromuscular sutures of 3-0 silk invert the chromic suture line.

reduced tissue manipulation, there is minimal edema with uniformity of suture placement, a wider lumen is constructed, there is greater ease and less time involved in performing the anastomosis, and the length of postoperative paralytic ileus is reduced. When they are placed in intestine through which urine traverses, however, stapled anastomoses using nonabsorbable staples frequently cause stone formation and should be avoided (Costello and Johnson, 1984; Woodhouse and Robertson, 2004).

The TA (transverse anastomosis) stapled anastomosis everts the suture line. Because staples close in a B configuration and do not crush the tissue, theoretically they prevent ischemia at the suture line. This may be obvious when a staple line is used to transect the bowel and bleeding continues to occur. The bleeding points may be lightly electrocoagulated or tied off with fine absorbable suture. Stapled bowel anastomoses have been shown to be as efficacious as hand-sewn anastomoses because both have similar complication rates. **They usually require less time to perform when the techniques are properly learned, but for prolonged procedures they save little if any time when the length of time for the whole procedure is taken into account.** In a large prospective, randomized trial in which a two-layer closure was compared with a staple closure, it was found that the complication rate was the same, but the time required to complete the stapled anastomosis was 10 minutes less than that for the hand-sewn anastomosis; when the total operative time was compared between the two, it was the same (Didolkar et al, 1986). **A comparison of complications between sutured and stapled anastomoses reveals a leak and fistula rate of 2.8% for stapled and 3% for sutured anastomoses (Chassin et al, 1978).** The clinically significant leak rate, however, is only 0.9% (Fazio et al, 1985). A 4.5% incidence of stapled anastomotic leakage has been reported during ileal conduit construction (Costello and Johnson, 1984).

Thus the use of staples or sutured anastomosis is at the discretion of the surgeon. A stapled anastomosis appears to be superior to a hand-sewn anastomosis in an esophageal-intestinal anastomosis and a low rectal anastomosis. In these two areas, the circular stapler allows a more precise anastomosis than is often possible with hand-sewing techniques. Because these are not problems of urologic surgery, staples are used if that is the preference of the surgeon. The one area in urology where I believe the stapling device is superior is in the ileocolonic end-to-side anastomosis. With use of the circular stapling device, a widely patent anastomosis can be achieved expeditiously.

Three staple instruments are commonly used in intestinal reconstruction: the linear stapler, the anastomotic stapler, and the circular stapler. The linear stapler places a double or triple row of staggered staples in a straight line. Depending on the cartridge and instrument chosen, various lengths of staple lines and heights of the closed staples may be chosen. The length is selected according to how long one wants the staple line to be. **The height of staple is selected according to the tissue to be stapled.** Vascular and pulmonary tissues require staples with a closed height of 1 mm (open height of 2.5 mm). Most intestinal anastomoses are performed with medium staples, which have a closed height of approximately 1.5 mm (open height of 3.5 mm). On occasion, for thick tissues, large staples are required that have a closed height of 2 mm (open height of 4.8 mm). If there is any doubt in selecting the staple size, the tissue thickness may be measured with a special instrument used for this purpose. In general, tissues less than 1 mm or more than 3 mm in thickness are not amenable to the use of staples. Recently, staplers with a variety of staple heights within the same cartridge have been introduced and should provide more safety in varying tissue thicknesses.

The anastomotic stapler places two linear double rows of staggered staples. When the knife is advanced, the staple line is divided. The height of the staples is also chosen according to the tissue to be transected.

The circular stapler places two concentric, staggered circular staple rows and cuts the tissue within the circle completely from the surrounding tissue. It may be selected in various diameters and with various heights of staples. The diameter and height are selected

according to the tissue to be anastomosed. The diameter to be selected is determined by sizing the diameter of the tissue to be stapled. Special sizers are available for this maneuver. In most intestinal anastomoses in urology, the height of the closed staple is 1.5 to 2 mm. The following is a description of various types of stapled anastomoses.

Ileocolonic Anastomosis with the Circular Stapling Device

The mesenteric borders are cleared for a distance of 1.5 cm from the cut end of both the colon and the ileum (Fig. 97-9). Holding sutures of 3-0 silk are placed on the mesenteric and antimesenteric border of the colon. Two other holding sutures are placed on the medial and lateral walls of the colon, midway between the mesenteric and antimesenteric sutures. A purse-string suture of 2-0 polypropylene (Prolene) is placed around the ileum no more than 2 mm from the cut end. It is important to take small bites of mucosa to avoid bunching of tissue. Sutures must be placed evenly to avoid a gap. A purse-string instrument can be used for this step, if preferred. The ileal diameter is determined with sizers so that the correct circular stapler diameter instrument may be chosen—usually 25 mm. A purse-string suture is also placed in a circle, 1 cm in diameter, through which a taenia traverses on the medial aspect of the colon. A stab wound is made in the center of the colonic purse-string suture. The distal anvil of the circular stapler is removed, and the instrument is placed through the open end of the colon with its post passed out the stab wound made in the center of the purse-string on the medial wall of the colon. The purse-string is tied tight. The top anvil is then secured to the post, and the ileum is placed over it. The ileal purse-string is tied.

Care must be taken to align the mesenteries at this point. The instrument is approximated with a staple gap of 1.5 to 2 mm. Care must be taken not to catch fat or mesentery in the gap. The instrument is fired and removed by rotatory movement from the colon. Two doughnuts of tissue should be identified on the instrument, and they should have their complete circumference intact with no gaps. With a finger in the open end of the colon and through the anastomosis, seromuscular sutures of 3-0 silk are placed 3 to 4 mm apart around the circumference of the anastomotic line.

Figure 97-9. Stapled circular anastomosis. A, A purse-string suture of 2-0 polypropylene (Prolene) is placed around the circumference of the small bowel, and a second purse-string suture 1 cm in diameter is placed on a medial taenia 5 to 6 cm from the open end of the colon. The anvil is removed. A stab wound is made in the center of the purse-string suture in the colon, and the circular stapler is introduced through the end of the colon, with its post thrust through the stab wound. B, The anvil is placed on the post and introduced into the end of the small bowel, the purse-string sutures in the small bowel and colon are tied snugly around the post, and the circular stapler is approximated with a gap of 1.5 to 2 mm, with care taken not to include any mesentery in the gap. The anastomosis is completed by placement of interrupted silk sutures around the circumference of the anastomosis.

The transected end of the colon may be closed by the suture technique or by the use of staples. If the end is to be closed with sutures, one 3-0 chromic suture is brought out the mesenteric border and another out the antimesenteric border, and both are tied to themselves with the knots on the inside of the bowel. The two sutures are run toward each other with a Connell stitch until they meet, and then they are tied to each other. The suture line is inverted by placement of a second row of 3-0 silk seromuscular sutures. If staples are preferred, the holding sutures are held up and a linear stapler is applied across the open end. Excess tissue is trimmed and the stapler removed. By holding the holding sutures up, one is secure in applying the staple line to the serosa and mucosa circumferentially around the bowel. Some invert the staple line with seromuscular sutures of 3-0 silk. This is not necessary, however. The mesentery between the two segments is now approximated with interrupted 3-0 silk sutures.

End-to-End Stapled Anastomosis: Ileal-Ileal or Ileocolonic Anastomosis

The antimesenteric border of the two bowel segments to be joined is approximated with a 3-0 silk suture 5 to 6 cm from the cut ends of the bowel (Fig. 97-10). A holding suture is placed through both

Figure 97-10. Stapled end-to-end anastomosis. A, A 3-0 silk suture is placed 5 to 6 cm from the cut ends of the intestine on the antimesenteric borders of both intestinal segments and tied. Holding sutures are placed around the circumference of both intestinal lumens, one suture securing together the antimesenteric borders of both intestinal segments. The linear anastomotic stapler is placed into the lumens, secured and locked in place, and fired. The knife is advanced. B, The appearance of the intestinal anastomosis after firing of the stapler device. C, The open end of the two intestinal segments is closed with a linear stapler by elevation of the holding sutures while the linear stapler is applied so that the circumferences of the mucosa and serosa are incorporated in the staple margin. D, The anastomosis is completed by closure of the mesentery with interrupted 3-0 silk sutures.

segments of bowel at their cut ends at the midpoint of the antimesenteric borders. Stay sutures are placed at the mesenteric border of each bowel segment, and two other sutures midway between the mesenteric and antimesenteric border on the lateral aspects of the bowel are also placed. The anastomotic stapler is positioned in the lumens of both segments of bowel along the antimesenteric border. The antimesenteric holding suture is pulled up adjacent to the stapler. The anastomotic stapler is locked in place, the staples are fired, and the knife is advanced. The staple lines are inspected for bleeders, which if persistent should be suture ligated with an absorbable suture. It is important for several 3-0 silk sutures to be placed at the apex of the stapled and cut antimesenteric incision. At this point, slight tension on the anastomotic line can place undue stress on the staple margin and cause a leak. The holding sutures are held up, and a linear stapler is placed across the open end of bowel and fired. Care must be taken so that the staples include the serosa in its entire circumference. Excess bowel tissue is excised flush with the instrument before it is disengaged. The mesentery is then reapproximated.

Laparoscopic and Robotic Anastomoses

Laparoscopic and robotic approaches to cystectomy and augmentation cystoplasty have been reported (Guilliotreau et al, 2009; Goh et al, 2012). In these procedures of urinary diversion with continent neobladder or ileal ureter substitution, a purely laparoscopic or robotic technique is possible for bowel resection with the use of endoscopic stapling devices. Proper placement of the trocars is dependent on the need to mobilize the bowel and the procedure for which the bowel is to be used. Trocar placement for mobilization of the distal ileum is illustrated in Figure 97-11. The technique primarily involves the use of endoscopic linear cutting and stapling devices, which can be used to divide small bowel and its mesentery (Figs. 97-12 and 97-13). Reanastomosis purely intracorporeally can be accomplished with the same endo-GIA stapler to reconstitute bowel continuity with a side-to-side functional end-to-end anastomosis (Gill et al, 2000; Potter et al, 2000). An endoscopic TA stapler may be used to complete the bowel closure.

A laparoscopic or robotic ileal conduit can be performed with these techniques. The ureterointestinal anastomosis is performed with freehand laparoscopic suturing. One of the abdominal trocar sites is used to draw the bowel segment through the abdominal wall for stoma construction. Completely laparoscopic orthotopic ileal neobladder has been reported (Gill et al, 2002). The neobladder is constructed by freehand running suture with use of laparoscopic techniques (Fig. 97-14). The results of laparoscopic bowel anastomoses suggest that these anastomoses are safe, but no large series

Figure 97-11. Trocar placement for laparoscopic mobilization of the distal ileum.

Figure 97-12. Laparoscopic mobilization of a small bowel segment for use in reconstruction. The visceral peritoneum is divided sharply; then the mesenteric vessels are ligated and divided. Staplers, ultrasonic shears, or bipolar cautery devices may be used to divide the mesenteric vessels.

Figure 97-13. The endoscopic gastrointestinal stapler divides the intestinal segment. The staple line must be excised from the segment intended for use in the urinary reconstruction.

that compares open with laparoscopic approaches for bowel anastomosis has been published (Canin-Endres et al, 1999; Rothenberg, 2002). Robotic surgical approaches to radical cystectomy and urinary diversion have become increasingly reported. A barbed monofilament suture may facilitate suturing of the neo-bladder (Tyrizis et al, 2013).

Other approaches to laparoscopic or robotic intestinal surgery include laparoscopic mobilization of the bowel segment and exteriorization of the segment; the anastomosis of the bowel and ureteral anastomoses are then performed in an open fashion through a small laparotomy incision (Fig. 97-15). This is now the preferred approach for many performing laparoscopic or robotic cystoprostatectomy. Purely laparoscopic intestinal anastomoses in radical cystectomy are associated with a much higher complication rate from intestinal and ureteral anastomotic leaks than an exteriorized approach (Stephenson and Gillis, 2008). In radical cystectomy, a small incision is already required for intact specimen removal. An open approach therefore allows direct tactile assessment of the anastomoses.

Figure 97-14. Many urologic procedures in which intestinal segments are used for reconstruction involve extirpative surgery in which a small laparotomy is used for specimen removal. In this case the small laparotomy is used to deliver the bowel segment outside the abdomen. Any form of anastomosis may be used by this technique, which also reduces the chance of spillage of intestinal contents.

Figure 97-15. Completely intracorporeal laparoscopic construction of a small intestinal neobladder; 2-0 polyglycolic acid suture is used in a running closure of the pouch.

Compression Anastomoses and the Biofragmentable Ring

There is a long history of experimental work on compression anastomoses. These technologies may facilitate natural orifice and minimally invasive surgery. With the most clinical evidence, the biofragmentable ring has proven safe, effective, and time efficient.

Several studies have shown that these intestinal anastomoses are as safe as hand-sewn or stapled anastomoses (Ghitulescu et al, 2003). Other compression devices have been devised but have not gained in popularity (Kaidar-Persno et al, 2008).

Postoperative Care

The patient should not be allowed to begin oral alimentation until bowel function returns after surgery. Coordinated small bowel activity begins within hours after the operative event, and stomach activity may return as early as 24 hours postoperatively. Clear liquids may be begun when the paralytic ileus resolves and bowel activity resumes. If clear liquids are tolerated, the diet may be advanced. This sequence of events generally takes 1 to 4 days. **If the nutritional condition of the patient is impaired preoperatively, a postoperative complication delays oral feeding, or the paralytic ileus is still present on the fifth postoperative day, the patient should receive intravenous nutrition that supplies the total calorie requirement (hyperalimentation). It is preferable to begin the hyperalimentation the day after surgery if any of these complications are anticipated.** Once started, it is discontinued only when oral intake is sufficient to satisfy the body's calorie requirements. Some have advocated the use of a jejunal feeding tube for the early institution of intestinal feeding (Maffezzini et al, 2008).

The use of nasogastric or gastrostomy decompression during the postoperative period of ileus is somewhat controversial. In a prospective study of elective intestinal anastomoses in which 274 patients had postoperative gastric decompression and 261 patients were given nothing by mouth until bowel activity resumed, there was no significant difference in major intestinal complications between the two groups; however, those who did not have gastric decompression showed a much greater incidence of abdominal distention, nausea, and vomiting. It must be understood that only healthy patients with no complications were entered into the study. Sixty percent of the patients initially entered were excluded. Specific exclusion criteria included emergency surgery with peritonitis, extensive fibrous adhesions, enterotomies, previous pelvic irradiation, intra-abdominal infection, pancreatitis, chronic obstruction, prolonged operating time, and difficult endotracheal intubation (Wolff et al, 1988). Meta-analysis of randomized studies of postoperative nasogastric decompression suggests that bowel function returns earlier without a tube. In this study, nonsignificant trends were seen toward fewer pulmonary complications but more wound complications when an NGT was not used (Nelson et al, 2005).

Because of the limitations in the available studies, it is still recommended to use nasogastric decompression in all but the most medically fit patients. Vomiting in the postoperative period increases the risk of aspiration and morbidity in the compromised patient. Moreover, tube decompression allows the administration of ice chips by mouth before enteric activity resumes, thus enhancing the patient's comfort. If the patient has severe pulmonary disease, decompression by placement of a gastrostomy tube at the time of surgery facilitates pulmonary toilet and enhances comfort. In patients who have significant comorbid conditions such as sepsis, consideration should be given to administration of an H₂ blocker and an antacid via the stomach tube every 2 hours as needed to keep the gastric pH above 5 during the period of ileus. By keeping the gastric contents alkaline in these critically ill patients in the postoperative period, the incidence of gastric stress ulceration is markedly reduced.

Because many studies have shown that the absence of an NGT in the postoperative period after intestinal surgery does not increase intestinal anastomotic complications compared with patients in whom NGTs are used, there is a trend to reduce the length of time the NGT is in place. In patients who underwent a radical cystectomy and who were given metoclopramide 10 mg intravenously every 6 hours, until taking fluids orally, Donat and colleagues (1999) found that three quarters of the NGTs could be removed in less than a day. Compared with the standard regimen of NGT drainage, the group given metoclopramide had a much earlier return of bowel function

(Donat et al, 1999). More recent studies also support the safety of early NGT removal (Park et al, 2005).

Complications of Intestinal Anastomoses

The complications that follow anastomoses include leakage of fecal contents, sepsis, wound infections, abdominal abscesses, hemorrhage, anastomotic stenosis, pseudo-obstruction of the colon (Ogilvie syndrome), and intestinal obstruction. These untoward events increase morbidity and are frequently major contributors to mortality (Hautmann et al, 2010). The complication rates for elective colocolonic and ileocolonic anastomoses performed in prepared bowel with contemporary technique are intestinal leak, 2%; hemorrhage, 1%; and stenosis or obstruction, 4%. These complications require reoperations in 1% of the patients and result in death in 0.2% of patients (Jex et al, 1987). The mean time to diagnose an anastomotic leak is 12 days postoperatively; some have occurred even after 30 days (Hyman et al, 2007). Many of the complications of radical cystectomy are attributable to the use of intestinal segments for urinary diversion (Takada et al, 2012).

Fistulas

Fistulas in the postoperative period are of two types, fecal and urinary. These generally occur within the first several weeks after the operative event. They frequently result in sepsis and markedly increase morbidity and mortality. Fecal fistulas occur in 4% to 5% of patients (Sullivan et al, 1980; Beckley et al, 1982). Sepsis is a common complication of these untoward events and carries with it a mortality of 2% (1 of 47 patients) (Hill and Ransley, 1983). In long-term evaluation, approximately 10% of urinary diversion patients will suffer from fistulas (Gilbert et al, 2013).

Sepsis and Other Infectious Complications

Wound infections, pelvic abscesses, and wound dehiscences may complicate the immediate postoperative period. Although wound dehiscences and pelvic abscesses are rare complications, morbid wound infections occur with an incidence of 5% (3 of 62 patients) (Loening et al, 1982). Many of these complications may be averted by operating on a properly prepared bowel, by walling off the intestine with Mikulicz pads while the anastomosis is being completed, and by irrigating the intestinal segment to be used in the reconstruction until it is free of any residual enteric contents before it is manipulated and its contents are spilled in the abdomen and pelvis. The overall septicemia rate after radical cystectomy is currently 3.6%, with a 17% mortality rate (Davies et al, 2009). When assessed for cumulative incidence of infectious complications, nearly 45% of patients after urinary diversion will require treatment (Gilbert et al, 2013).

Bowel Obstruction

The incidence of intestinal obstruction after abdominal procedures for urinary intestinal diversion differs according to whether the stomach, ileum, or colon is used for the diversion. In patients who have had a segment of stomach or ileum removed for the diversion, there is a 10% incidence of postoperative bowel obstruction requiring treatment. When the colon is used, the incidence of postoperative obstruction requiring an operation is 5% (Table 97-3). Half of the bowel obstructions occur in the early postoperative period. In one series, after radical cystectomy and ileal conduit, 15% of the patients had a mild obstruction in the first 6 months that responded to conservative management, whereas 3% required an operation to relieve the obstruction during this period. The occurrence of obstruction after this 6-month period was much less frequent (Sullivan et al, 1980). More recently, a 10.5% incidence of reoperation for bowel obstruction was noted in a large series of radical cystectomy patients (Varkarakis et al, 2006). Bowel obstruction can be a morbid event: A significant number of patients who develop obstruction after an ileal conduit and require an

Data is from the following sources, which can be found in this chapter's reference list on the Expert Consult website: Jaffe et al, 1968; Castro and Ram, 1970; Malek et al, 1971; Smith, 1972; Schmidt et al, 1973; Richie, 1974; Flanigan et al, 1975; Schwarz and Jeffs, 1975; Shapiro et al, 1975; Middleton and Hendren, 1976; Althausen et al, 1978; Elder et al, 1979; Hagen-Cook and Althausen, 1979; Pitts and Muecke, 1979; Sullivan et al, 1980; Beckley et al, 1982; Loening et al, 1982; Adams et al, 1988; Boyd et al, 1989; Madersbacher et al, 2003; Studer et al, 2006; Nieuwenhuijzen et al, 2008.

operation die. The most common cause of the obstruction is adhesions, followed by recurrent cancer. These two causes account for the great majority of the cases. Volvulus and internal hernia account for far fewer cases (Jaffe et al, 1968). Rarely, severe stenosis or obstruction at the anastomotic suture line occurs. Stenosis is a result of edema, poor technique, or performing the anastomosis on ischemic bowel (Fig. 97-16); obstruction is a result of improper technique.

The incidence of postoperative bowel obstruction may be reduced by using nonirradiated bowel, performing the anastomosis on well-vascularized bowel, closing all apertures, reperitonealizing the isolated segment, decompressing the gastrointestinal tract for an adequate time, placing omentum over the anastomosis, and reconstituting the pelvic floor after exenterative surgery. Orthotopic neobladders appear to result in fewer bowel obstructions than ileal conduits or cutaneous reservoirs (Van Hemelrijck et al, 2013). The isolated segment is reperitonealized by tacking its antimesenteric border to the lateral abdominal sidewall peritoneum. The proximal mesenteric border should be tacked to the posterior parietal peritoneum because failure to obliterate this potential space has resulted in entrapment of bowel, causing a bowel obstruction. Placing the sigmoid colon in the area may close

the pelvic space left after an anterior exenteration. This effectively prevents small bowel from herniating into the raw pelvis. Omentum may also be mobilized and used to fill any space the sigmoid colon does not fill. In a total exenteration, sufficient sigmoid colon is not available and the omentum is often not bulky enough to fill the pelvis and thus prevent small bowel from filling the denuded pelvis. This situation is of particular concern in patients who must receive postoperative pelvic irradiation. The bowel may be kept out of the pelvis in these patients by reconstructing the pelvic floor with polyglactin mesh. The mesh is sutured along the posterior pelvic brim to the sacral promontory and presacral fascia and laterally to the adventitia of the iliac vessels. Laterally and anteriorly, it is sewn to the peritoneum two thirds of the distance between the pubis and umbilicus. Omentum is then brought down, placed over the mesh, and sutured in position. This effectively excludes the bowel from the pelvis for 4 to 6 weeks while postoperative irradiation is being administered (Sener et al, 1989).

Hemorrhage

Hemorrhage is a rare complication of intestinal anastomoses. It is much more likely to occur when stomach is used and a Billroth I

Figure 97-16. Upper gastrointestinal tract series illustrates a small bowel stricture (arrow) at the ileoileostomy after ileal conduit urinary diversion. At the time of the initial ileoileostomy, the anastomotic suture line appeared bluish. At subsequent exploration, a bowel lumen of only 2 mm was found. The serosa at the anastomotic site was fibrotic.

anastomosis is constructed. It is usually caused by failure to secure bleeding at the time of anastomosis or anastomotic ulcers that develop on the suture line.

Intestinal Stenosis

Intestinal stenosis occurs at two distinct times: in the immediate postoperative period and during the long term. Intestinal stenosis in the immediate postoperative period is caused by technical mishaps or edema. Edema resolves by continuing the intestinal decompression, whereas technical mishap requires a reoperation. During the long term, it is likely caused by ischemia or perienteric infection. [Figure 97-16](#) shows an upper gastrointestinal tract series of a severe intestinal stenosis caused by ischemia. At the time of the ileoileostomy, the suture line was blue. Chronic symptoms of partial small bowel obstruction occurred in the postoperative period.

Pseudo-Obstruction

Pseudo-obstruction of the colon, or Ogilvie syndrome, on rare occasion may complicate the early postoperative period. Its cause is not understood. **Pseudo-obstruction usually occurs within the first 3 days postoperatively in patients with multiple medical illnesses.** The patient develops severe abdominal pain, and a radiograph of the abdomen reveals a dilated cecum. A gentle water-soluble contrast enema eliminates the possibility of a mechanical obstruction. In the presence of a rising leukocyte count or cecum that is increasing in size and exceeds 12 to 15 cm in diameter, rupture may be imminent. Under these circumstances, an emergency cecostomy should be performed ([Clayman et al, 1981](#)). In less acute circumstances, endoscopic decompression may be attempted ([DeGiorgio and Knowles, 2009](#)).

Figure 97-17. Volvulus of an orthotopic right colon bladder. This segment enlarged markedly because of the patient's lack of adherence to a regimen of frequent intermittent catheterization.

Complications of the Isolated Intestinal Segment

Intestinal Stricture

Strictures of intestinal segments are usually late complications primarily occurring in conduits, although they have been described in ileal ureters as well. **The stricture is thought to be a consequence of lymphoid depletion of the intestine exposed to urine.** The lymphoid depletion contributes to persistent infection, which may result in midloop stricture, bacterial seeding of the upper tracts, and renal deterioration ([Tapper and Folkman, 1976](#)). Because of the persistent infection and lack of intestinal resistance to the detrimental action of bacteria, submucosal edema with fibrosis and stricture formation occurs. The intestinal segment may also be blocked by encroachment of hypertrophied mesenteric lymph nodes. **Hypertrophied mesenteric lymph nodes, submucosal lymphoid depletion, edema, and fibrosis are commonly found when intestinal segments that have been chronically exposed to urine are examined pathologically.**

Elongation of the Segment

Another complication of the intestinal segment is elongation, occasionally resulting in massive enlargement. When this occurs in conduits or ureteral substitutes, there is usually a distal obstruction. In continent diversions, it may signal failure to catheterize the pouch frequently enough. If allowed to persist, the increased pressure may result in deterioration of renal function. Enlargement and elongation of the intestine may also result in a volvulus of the segment ([Fig. 97-17](#)).

Abdominal Stomas

Two types of stomas may be made on the anterior abdominal wall: those that are flush with the skin and those that protrude. The flush

stoma is preferable for the continent type of diversion in which intermittent catheterization is carried out and over which a small dressing is placed. The stoma that protrudes is preferable when a collection device is worn. **A properly protruding stoma worn with an appliance results in a lesser incidence of stomal stenosis and a better appliance fit with fewer peristomal skin problems. There are two types of protruding stomas: the end stoma and the loop end ileostomy. Most complications of stomas are the result of technical errors in their construction. Therefore to minimize such complications, specific technical points must be rigidly followed.**

The site of the stoma should be selected preoperatively. This is done by marking the stomal site with the patient in the sitting position, as well as in the supine position; care is taken to place it over the rectus muscle at least 5 cm away from the planned incision line. The point chosen should be well away from skin creases, scars, the umbilicus, belt lines, and bone prominences. A site in which radiotherapy has previously injured the area should be avoided. **All stomas should be placed through the belly of the rectus muscle and be located at the peak of the infraumbilical fat roll.** If the stoma is placed lateral to the rectus sheath, a parastomal hernia is likely to occur. The bowel should traverse the abdominal wall perpendicular to the peritoneal lining (i.e., it should come straight out). One should avoid trimming fat or epiploic appendages from around the margin of the stoma, and the appliances should be applied in the operating room.

The stoma should be brought through a circular incision made at the predetermined site. A perfectly circular opening in the skin may be made by placing the finger hole of a Kelly clamp at the desired point and grasping the skin in the center of the hole with a Kocher clamp. Pulling up on the Kocher clamp and pushing the handle of the Kelly clamp against the abdominal wall allows for a small button of skin to be removed with a single pass of the knife. This makes a perfectly circular opening in the skin. However, the tendency to remove too much skin is great, resulting in a circular opening that is too large. To avoid this complication, one should not cut the skin flush with the Kelly clamp but rather immediately beneath the Kocher clamp. The subcutaneous tissue is left intact. This is spread, not excising any fat, because the fat falls back adjacent to the bowel and eliminates any dead space. Kocher clamps are placed on the fascia in the incision and pulled medially so that when the fascia and peritoneum are incised, they are incised directly over the skin line and thus do not result in angulation of the gut when the abdominal incision is closed. The fascia is incised in a cruciate manner, and the rectus muscles are spread. The peritoneum is incised. The opening should accommodate two fingers snugly.

Nipple Stoma: "Rosebud"

A Babcock clamp is placed through the opening, and the bowel is grasped and brought out for a distance of 5 to 6 cm to make a nipple of about 2 to 3 cm in length (Fig. 97-18). Two 3-0 chromic sutures are placed through the seromuscular layer of the bowel and

Figure 97-18. A and B, Nipple stoma. Five to 6 cm of intestine are brought through the abdominal wall. The serosa is scarified, and quadrant 3-0 chromic sutures are placed through the full thickness of the distal end of the intestine. Each suture is placed in the seromuscular layer 3 cm proximal and then secured to the dermis before it is tied.

the peritoneum on the anterior abdominal wall. Alternatively, the serosa may be sutured to the fascia with two 2-0 chromic sutures. The mesentery is aligned in its normal anatomic direction before the serosa is sutured to the peritoneal wall. The ileum is usually curved in a concave manner toward the mesentery. If the curvature is severe, the mesentery may be partially incised 1 cm from the bowel wall (Fig. 97-19). Thus a portion of mesentery is preserved along the entire length of the bowel. This should straighten the curve in the bowel significantly if not completely. Four 3-0 chromic sutures are placed in quadrants through the full thickness of the bowel edge and through the seromuscular layer of the bowel 3 to 4 cm from the cut edge and then through the subcuticular skin layer. Sutures should not traverse the full thickness of the skin but should be placed through the subcuticular and subdermal layers only.

When the sutures are tied, the bowel is everted and forms a nipple. A more secure nipple may be made by performing multiple myotomies through the seromuscular layer of the bowel above the skin line before construction of the nipple. The myotomies adhere serosa to serosa and reduce the risk of stomal retraction. This is particularly appropriate for patients who are obese.

Flush Stoma

Quadrant sutures of 3-0 chromic are placed through the full thickness of the bowel and subsequently passed through the subdermal layer of the skin and tied. Several sutures are placed between the quadrant sutures from bowel to subdermal skin. This constructs a flush stoma that has a 1-mm raised margin.

Loop End Ileostomy

Obese patients have a thick abdominal wall and often a thick, short ileal mesentery. This makes construction of an end ileal stoma extremely difficult. **The loop end ileostomy obviates some of these problems and is usually easier to perform than the ileal end stoma in the patient who is obese (Fig. 97-20).** To construct this type of stoma, the distal end of the ileum is closed as described previously for closing the proximal end of an intestinal segment, and a loop is brought up through the belly of the rectus muscle and onto the anterior abdominal wall. This avoids bringing the mesenteric border onto the abdominal wall and prevents one side of the ileostomy from being involved with mesentery. A slightly larger skin opening is required than for the end stoma. A 3-cm disk of skin is

Figure 97-19. If it is tethered by the mesentery, the bowel may be straightened by incising the mesentery several centimeters away from the serosa and parallel to the bowel.

Figure 97-20. Loop end ileostomy. A, After the distal end of the loop is closed and the bowel is drawn through the rent in the abdominal wall, the bowel is held in place by a rod passed through the mesentery. The mesentery is realigned, and the peritoneum is sutured to the serosa of the bowel circumferentially. B, A transverse incision is made in the bowel four fifths of the loop distance cephalad. C, The cephalad portion of the stoma is simply sutured to the dermal layer of skin with interrupted 3-0 chromic sutures. D, On the inferior aspect of the incision, 3-0 chromic sutures are placed through the full thickness of the cut edge, then through the seromuscular layer, and then through the dermis. This everts the caudal portion of the stoma.

removed. The subcutaneous tissue is spread, the fascia incised, the rectus spread, and the peritoneum incised as described earlier. The opening should admit two fingers comfortably. The loop may be pulled through the opening in the abdominal wall by passing an umbilical tape through a small opening in the mesentery at a distance from the distal end that is sufficient to leave that end in the abdomen when the loop has been pulled through the abdominal wall. By gentle traction on the umbilical tape, the loop is brought onto the abdomen.

The distal portion of the bowel is brought through the opening such that the closed end lies cephalad to the body of the segment. When a sufficient amount of loop protrudes beyond the skin edge, a small rod is placed through the hole in the mesentery at the apex of the loop and holds the bowel on the anterior abdominal wall during suturing. If the rent in the rectus muscle is too large, it may be closed with interrupted 0 chromic sutures from within the abdomen. The serosa is sutured to the peritoneum on the anterior abdominal wall. The bowel wall is opened in a transverse direction at a point four fifths of the distance cephalad to the most caudal portion of the loop. With 3-0 chromic sutures, the full thickness of the caudal incision in the bowel is sutured back to itself (serosa) and then to the dermis as in the rosebud technique. The cephalad nonfunctional opening is sutured directly to the dermis. The rod is sutured to the skin and left in place for 7 days.

The Turnbull loop stoma results in a lesser incidence of stoma stenosis but a higher incidence of parastomal hernias (Emmott et al, 1985). Overall, the two types of stoma are functionally equivalent over time (Chechile et al, 1992). Stomas for the colon may be constructed in much the same way as end stomas for the ileum. Their suturing, however, is usually more flush than everted.

Complications of Intestinal Stomas

Complications of the abdominal stoma are the single most common problem encountered in the postoperative period after urinary intestinal diversion. Early complications of abdominal

stomas include bowel necrosis, bleeding, dermatitis, parastomal hernia, prolapse, obstruction, stomal retraction, and stomal stenosis. At some point, virtually every patient has one of these complications. Many of these complications can be reduced by proper construction of the stoma. If periodic visits to the enterostomal therapist are made, products for skin care are appropriately used, nonirritative stomal adhesives are used, the urine in the collection device is maintained acidic, and properly fitting collection devices are used, most stomal complications can be significantly reduced and many eliminated.

Parastomal skin lesions may be classified as irritative, which are manifested by hypopigmentation, hyperpigmentation, and skin atrophy; erythematous erosive lesions, which appear as macular lesions, scaling of the skin, and loss of the epidermis; and pseudoverrucous, which are wartlike lesions (Borglund et al, 1988).

Stomal stenosis has been reported, on average, in 20% to 24% of patients with ileal conduits and 10% to 20% of patients with colon conduits (see Table 97-3). This incidence has been considerably reduced by better attention to stomal care and better-fitting appliances (Eisenberg et al, 2014). Stomal stenosis is less for loop stomas than for end stomas. Parastomal hernias occur rarely (1% to 4%) with end stomas but are more likely to occur with loop stomas, with reported incidences ranging from 4% to 20%. Incidence of stenosis of catheterizable stomas is high, reaching more than 50% in children (Barqawi et al, 2004). Stoma-related complications appear to be more common in an umbilically placed stoma versus one in the abdominal wall (De Ganck et al, 2002). Others have reported excellent long-term results with few complications in the concealed umbilical stoma (Glassman and Docimo, 2001).

Bleeding, stomal stenosis, and dermatitis can be markedly reduced by attention to parastomal skin care and by the use of a properly fitting appliance around a protruding stoma. The other complications are minimized by proper surgical technique.

Parastomal hernia occurs frequently after ileal loop urinary diversion, with an incidence of 2% to 6.6% (Gilbert et al, 2013). It can be effectively treated with open repair (Franks and Hrebinko, 2001; Ho and Fawcett, 2004). Laparoscopic approaches have also been reported with mixed results. One series reported a 56% failure rate within 6 months of laparoscopic parastomal hernia repair with Gore-Tex mesh (Safadi, 2004). This contrasts with the high success rate reported in another small series (Kozlowski et al, 2001).

Massive bleeding from the conduit occasionally occurs, usually as a result of varices. There have been several interesting reports of patients who have developed ileal conduit varices generally as a result of hepatic dysfunction and portal hypertension. Treatment by transhepatic portal-systemic shunt and transhepatic angiography and embolization is a relatively minimally invasive technique that has promise, and its use is worthwhile in these difficult patients (Lashley et al, 1997; Medina et al, 1998).

URETEROINTESTINAL ANASTOMOSES

The ureter may be anastomosed to the colon or small bowel in a refluxing or nonrefluxing anastomosis. There is considerable controversy as to whether a nonrefluxing or refluxing anastomosis is desirable in urinary tract reconstruction. Regardless of type of diversion, renal failure has been seen in 12.5% of patients over the long term (Gilbert et al, 2013). Deterioration of the upper tracts for ileal and colon conduits has been reported in 10% to 60% of the patients (Koch et al, 1992; Samuel et al, 2006). In one series, 49% of the upper tracts showed changes after conduit diversion, 16% of which had an increase of the blood urea nitrogen of 10 mg/dL or more (Schwarz and Jeffs, 1975). Deterioration of the upper tracts is usually a consequence of lack of ureteral motility, infection, or stones and less commonly caused by obstruction at the ureteral-intestinal anastomosis. Because bacteriuria occurs in almost all conduits and because the intestine certainly does not inhibit and may, in fact, promote bacterial colonization, many have suggested that a nonrefluxing anastomosis would minimize the incidence of renal deterioration.

The evidence that suggests a nonrefluxing system in urinary intestinal diversions is desirable comes from several observations. In a group of patients who had nonrefluxing colon conduits constructed, those whose anastomoses remained nonrefluxing had a lesser incidence of renal deterioration than did those in whom the antireflux anastomosis failed. Follow-up for 9 to 20 years revealed that 79% (22 of 28 patients) of the refluxing renal units deteriorated, whereas only 22% (11 of 51 patients) of the nonrefluxing units deteriorated (Elder et al, 1979; Husmann et al, 1989). Others have reported that in continent diversions, the majority of patients who experience reflux show upper tract dilation and deterioration, whereas few show upper tract deterioration when a nonrefluxing anastomosis is present (Kock et al, 1978). Similar findings have been reported in experimental animals.

If a nonrefluxing ureteral-colonic conduit diversion is constructed, only 7% of the renal units show evidence of pyelonephritic scarring after 3 months. If a refluxing anastomosis is constructed, 83% of the renal units show scarring. Half of the conduits in both groups have significant bacteriuria (Richie and Skinner, 1975). Others have not found the same high incidence of renal deterioration associated with ureteral-intestinal reflux. One group of investigators studying colon conduits noted no difference in the incidence of renal deterioration regardless of whether the colon conduit demonstrated reflux; 17% (5 of 29) of nonrefluxing renal units showed deterioration compared with 18% (5 of 27) of refluxing units (Hill and Ransley, 1983). In another series, only 3 of 135 renal units with refluxing ureteral-intestinal anastomoses that were unobstructed showed evidence of renal deterioration (Shapiro et al, 1975). A more recent study compared refluxing and nonrefluxing ureteral-intestinal anastomoses in 58 patients with conduit diversions; 56 renal units were refluxing and 60 renal units were nonrefluxing. There was no difference in renal deterioration or in pyelonephritis between the two groups. Ureteral-intestinal stricture formation occurred in 2% of refluxing units as opposed to 13% of nonrefluxing units (Pantuck et al, 2000). A high-capacity, low-pressure reservoir may not require antirefluxing anastomoses (Hohenfellner et al, 2002).

It does not appear that conduit pressures are transmitted to the renal pelvis. The pressure within the renal pelvis in refluxing conduit diversions is not elevated above normal, and it is not dependent on the segment of bowel used (i.e., ileum or colon) (Magnus, 1977; Kamizaki and Cass, 1978; Hayashi et al, 1986). Peristaltic ureteral contractions apparently dampen pressure transmission from intestine to renal pelvis, attesting to the importance of normal ureters. When bowel is substituted for the ureter, it does not appear that it makes any difference whether there is reflux at the bladder. The voiding pressure is blunted by the distensible bowel segment. Indeed, in one study of continent diversions in which a segment of ileum formed the pouch to which the ureters were anastomosed, radionuclide voiding cystography failed to detect reflux to the kidneys (Waidelich et al, 1998). Moreover, there is no difference in ileal and colon conduits between those who experience reflux and those who do not in renal function measured 2 to 5 years postoperatively (Mansson et al, 1984). Also, the successful construction of an antirefluxing anastomosis does not prevent bacterial colonization of the renal pelvis. In six of eight patients with nonrefluxing enterocystoplasties and one patient with a nonrefluxing colon conduit in whom the absence of reflux was documented by loopogram, percutaneous renal pelvic aspiration revealed positive cultures (Gonzalez and Reinberg, 1987). One stated advantage of a refluxing anastomosis in patients who have urothelia and are prone to malignant change is that the upper tracts may be observed by periodic introduction of contrast material into the conduit. From these studies, it appears that reflux associated with impaired ureteral peristalsis in the presence of bacteriuria or obstruction results in renal deterioration, but it has not been established for either conduit or continent diversions that reflux associated with the normal ureter in the absence of obstruction is detrimental to the adult kidney.

Although many techniques have been described to make the various types of ureterointestinal anastomoses, certain basic surgical principles are germane to all the anastomoses regardless of type. Only as much ureter as needed should be mobilized so that there is no redundancy or tension on the anastomosis. Mobilization should not strip the ureter of its periadventitial tissue because it is in this tissue that the ureter's blood supply courses. The ureter should be cleaned of its adventitial tissue only for 2 to 3 mm at its most distal portion where the ureter-intestinal mucosa anastomosis is to be performed. The ureterointestinal anastomosis must be performed with fine absorbable sutures, which are placed so that a watertight mucosa-to-mucosa apposition is constructed. The bowel should be brought to the ureter and not vice versa (i.e., the ureter should not be extensively mobilized so that it can be brought into the wound to the bowel lying on the anterior abdominal wall). At the completion of the anastomosis, the bowel should be fixed to the abdominal cavity, preferably adjacent to the site of the ureterointestinal anastomosis. If possible, the anastomosis should be retroperitonealized or a pedicle flap of peritoneum should be placed over the anastomosis.

In those diversions in which the intestinal stoma is brought to the abdomen and the proximal end of the bowel fixed to the retroperitoneum, there are two places where the bowel may be conveniently fixed to the retroperitoneum without jeopardizing mesenteric blood supply. The most convenient point of fixation is below the root of the small bowel mesentery at the level of the pelvic brim. The ureterointestinal anastomosis may be retroperitonealized at the level of the pelvic brim, thus fixing the bowel segment to the posterior body wall. In situations in which the ureters are short, a more cephalad fixation to the posterior peritoneum may be accomplished by placing the proximal end in the right upper quadrant cephalad to the takeoff of the right colic artery and immediately below the duodenum. This is a relatively avascular area and places the intestine fairly close to the right and left kidneys, thus reducing the length of ureter required to reach the intestinal segment.

Perhaps one of the most difficult complications of ureterointestinal anastomoses to manage is a stricture. In general, strictures are caused by ischemia, a urine leak, radiation, or infection. The incidence of urine leak for all types of ureterointestinal anastomoses is 3% to 5% (see Table 97-3). This incidence of leak can be reduced nearly to zero if soft Silastic stents are used. In one series of ureterointestinal anastomoses done at the same institution, the nonstented group had a 2% anastomotic leak and a 4% stricture rate. When non-Silastic rigid stents were used, there was a 10% incidence of stricture. When a soft Silastic stent was used, however, there were no strictures or leaks (Regan and Barrett, 1985). In a similar series in which colon conduits were constructed after gynecologic exenterative operations, the nonstented group had an 18% leak rate and an 18% stricture rate, whereas those who had been stented had a 3% leak rate and an 8% stricture rate (Beddoe et al, 1987). Early postoperative metabolic complications were reduced in a randomized study of stented versus nonstented anastomoses (Mattei et al, 2008). Thus the evidence indicates that modern soft Silastic stents are effective in reducing the leak rate, subsequent stricture formation, and postoperative complications. Better technique and better suture materials have also reduced the incidence of stricture in nonrefluxing anastomoses. In a series of nonrefluxing ureterocolonic anastomoses, researchers reported an 8% incidence of stricture formation (Stein et al, 1996b).

In constructing a submucosal tunnel in those procedures in which a nonrefluxing anastomosis is made, it is often helpful to inject saline with a 25-gauge needle submucosally to raise the mucosa away from the seromuscular layer. This makes dissection considerably easier (Menon et al, 1982).

These principles of surgical technique are common to all ureterointestinal anastomoses. Each type of ureterointestinal anastomosis, however, has specific technical points unique to its construction. Techniques involving ureterocolonic anastomoses are discussed first, followed by ureter-small bowel anastomoses.

Ureterocolonic Anastomoses

Combined Technique of Leadbetter and Clarke

The combined technique of Leadbetter and Clarke establishes a nonrefluxing ureterocolonic anastomosis by using a submucosal tunnel. The technique combines the ureterocolonic anastomosis of Nesbit, which is a refluxing elliptical anastomosis to the intestine, with the tunneled technique of Coffey (Fig. 97-21) (Leadbetter and Clarke, 1954).

The anterior taenia is incised obliquely for 2.5 to 3 cm as close to the mesenteric border as possible. The mucosa is dissected off

the muscularis for the entire length of the incision. At the distal end of the incision in the taenia, the mucosa is picked up with a fine Adson forceps, and a small button is excised. The ureter is spatulated for 5 to 7 mm such that an elliptical anastomosis may be made. The ureter is sewn mucosa to mucosa with 5-0 polydioxanone sutures (PDS) by either interrupted sutures with the knots tied on the outside or a running suture. If the suture line is to be run, it is wise to begin the anastomosis at the apex of the ureter. This suture is tied, and the posterior row is run to the most distal portion of the ureter, which is subsequently tied. A second running suture completes the anterior aspect. The seromuscular layer is then reapproximated loosely over the ureter in such a way as to allow “the ureter [to] lie in the bowel as a hammock without being compressed” (Leadbetter and Clarke, 1954). The bowel should be fixed to the peritoneum so that there is no tension on the ureters.

The complications reported with this procedure include a leak rate of 2.5%; deterioration of the upper tracts, which varies from 4.3% to 25%; and a stricture rate that varies from 8% to 14% (Table 97-4).

Transcolonic Technique of Goodwin

The transcolonic technique of Goodwin establishes a nonrefluxing ureterocolonic anastomosis by construction of a submucosal tunnel (Fig. 97-22). By this technique, the anastomosis is performed from within the bowel (Goodwin et al, 1953). If it is performed in bowel in continuity with the gastrointestinal tract, a noncrushing occlusive clamp is applied across the bowel cephalad to the desired point of the ureterointestinal anastomosis. This clamp is placed loosely about the bowel so as not to occlude the arterial supply in the mesentery.

A vertical incision is made in the bowel anteriorly, and the desired point of entrance of the ureter into the bowel is identified. A 0.5-cm incision is made in the posterior mucosa, and with use of a curved hemostat the mucosa is dissected from the submucosal layer in an oblique fashion coursing from medial to lateral. The hemostat is passed beneath the mucosa for a distance of approximately 3 to 4 cm and then brought through the serosa. A traction suture that has been placed on the ureter is then grasped with the hemostat, and the ureter brought into the colon. Both ureters should be brought into the bowel before they are sutured to the mucosa. The ureters should lie without tension or angulation. A No. 5 feeding tube is passed through the ureter to be sure that there is no kinking as it passes through the bowel wall. The redundant ureter is excised, and its end is spatulated and sewn with interrupted 5-0 PDS to the mucosa, with care taken to include with the mucosa some muscularis so that the ureter is securely fixed in place. A Silastic stent is placed up both ureters. As the ureters come through

Figure 97-21. Leadbetter-Clarke ureterointestinal anastomosis. **A**, Injection of the submucosal tissues with saline facilitates the dissection. **B**, A linear incision is made in the taenia, the taenia is raised, and the mucosa is identified. A small button of mucosa is removed, and the ureter is spatulated and then sutured to the mucosa with 5-0 polydioxanone sutures. The seromuscular layer is sutured over the ureter, with care taken not to compromise or occlude the ureter.

Figure 97-22. Transcolonic technique of Goodwin. **A**, The bowel is opened on its anterior surface; a small rent in the mucosa is made; and with a mosquito hemostat, the mucosa is raised from the submucosa extending laterally. A 3- to 4-cm tunnel is made before the clamp exits the serosal wall. The ureter is grasped and pulled into the submucosal tunnel. **B**, Both ureters have been drawn into the bowel through their submucosal tunnels before each is spatulated and circumferentially sutured to the mucosa. These sutures should also incorporate a portion of the muscularis for security. Where the ureter enters the colonic sidewall adjacent to the mesentery, the adventitia of the ureter is secured to the colonic serosa with interrupted 5-0 polydioxanone sutures.

Figure 97-23. Strickler ureterointestinal anastomosis. **A**, A small linear incision is made in the taenia, and the submucosa is dissected from the mucosa laterally. After a distance of 3 to 4 cm has been achieved, a small hole is made in the serosa and the ureter is drawn through. **B**, A button of mucosa is excised, and the ureter is spatulated and sutured to the mucosa with 5-0 polydioxanone sutures. The rent in the taenia is closed with interrupted sutures, and an adventitial suture at the ureter's entrance point into the colon secures it to the serosa of the colon.

the serosa from without the bowel, the adventitia of the ureter is sutured to the serosa of the colon with two 4-0 PDS sutures. The anterior bowel wall is closed in two layers.

The reported results with this technique appear to be satisfactory. However, specific reliable data on the complication rate are not available.

Strickler Technique

The Strickler technique establishes a nonrefluxing ureterocolonic anastomosis by construction of a submucosal tunnel (Fig. 97-23) (Strickler, 1965; Jacobs and Young, 1980). A 1-cm incision is made on the margin of the taenia. The technique originally described removal of a 2-mm button of seromuscular tissue. A 2-cm tunnel is formed laterally beneath the seromuscular layer

Figure 97-24. Pagano ureterointestinal anastomosis. **A**, A linear incision is made in the taenia between 4 and 5 cm in length. **B**, The submucosa is dissected from the mucosa laterally on both sides to the level of the mesentery. The ureters are drawn into the submucosal tunnel distally and sutured to the mucosa with 5-0 polydioxanone sutures proximally. **C**, The serosa is reapproximated, with incorporation of the mucosa in the midline.

with a hemostat. The seromuscular layer is incised, with care taken not to tent up the mucosa and inadvertently incise it. The holding suture in the ureter is grasped and drawn throughout the submucosal tunnel. The ureter is spatulated for 0.5 cm. A button of mucosa is removed, and the full thickness of the ureter is sewn to the mucosa of the bowel with either interrupted or running 5-0 PDS. The serosa is reapproximated over the ureter with 4-0 silk sutures. The serosal suture line is perpendicular to the course of the ureter. Where the ureters enter the serosa, they are also fixed with interrupted 4-0 PDS sutures. A lateral peritoneal flap is placed over the anastomosis.

The advantage of this anastomosis is that because the taeniae do not need to be aligned, one can form the tunnel according to the normal course of the ureter and avoid angulation. This technique reliably prevents reflux but results in a stricture rate of approximately 14% (see Table 97-4).

Pagano Technique

The Pagano technique establishes a nonrefluxing ureterointestinal anastomosis by construction of a submucosal tunnel (Fig. 97-24) (Pagano, 1980). The taenia is incised for a length of 4 to 5 cm, and the seromuscular layer is separated from the mucosa on both sides of the taenia laterally as far as the mesenteric border. The ureter is brought in one end (i.e., the distal end) laterally and laid in the 4- to 5-cm tunnel paralleling the mesenteric border. A button of mucosa is excised, and the ureters are spatulated and sutured to the mucosa with either interrupted or running 5-0 PDS. The seromuscular layer is then closed loosely with silk sutures in the midline. Each suture includes the seromuscular layer of the taenia and the mucosa in the midline.

This technique has a reported low complication rate. The leakage rate is approximately 3%, the stricture rate is 6%, and the reflux rate is approximately 6% (see Table 97-4) (Pagano et al, 1984).

Cordonnier and Nesbit Techniques

The Cordonnier and Nesbit techniques use no tunnel and are direct refluxing anastomoses of the ureter to the colon (Nesbit, 1949; Cordonnier, 1950). They are not desirable for ureterosigmoidostomies. They are performed in much the same way as a Bricker anastomosis would be performed for the small bowel (see later).

Small Bowel Anastomoses

There is a variety of ureter–small bowel anastomoses, which are of two basic types: end to side, and end to end. The end-to-side anastomoses may be constructed in a refluxing or nonrefluxing manner.

Bricker Anastomosis

The Bricker anastomosis is a refluxing end-to-side ureter–small bowel anastomosis that is simple to perform and has a low complication rate (Fig. 97-25) (Bricker, 1950). Although originally described for the small bowel, it may be used in any suitable intestinal segment.

In the original description, the adventitia of the ureter was sutured with interrupted silk sutures to the serosa of the bowel. The mucosa and serosa were incised; a small mucosa plug was removed; and with fine absorbable chromic sutures, the full thickness of the ureter was sewn to the mucosa of the bowel. The anterior layer of ureteral adventitia was then sewn with interrupted silk sutures to the serosa of the bowel. A less cumbersome method of performing this anastomosis is to excise a small button of seromuscular tissue and mucosa, spatulate the ureter for 0.5 cm, and suture the full thickness of the ureter to the full thickness of the bowel (i.e., mucosa and seromuscular layer to ureteral wall) with either interrupted or running 5-0 PDS. The anastomosis is stented with a soft Silastic catheter.

The stricture rate for this anastomosis varies from 4% to 22% (average of 6%). The leak rate is approximately 3% in the absence of stents (see Table 97-4). Open and robotic approaches have a comparable stricture rate (Anderson et al, 2013).

Wallace Technique

A frequently used anastomotic technique is that of Wallace, in which the end of the intestine is sutured to the end of the ureter (Fig. 97-26) (Wallace, 1970; Albert and Persky, 1971). This is a refluxing anastomosis. The intestinal segment used may be either small bowel or colon. There are three basic types of anastomoses:

1. The end of one ureter is sutured to the end of the other ureter, and this composite anastomosis is sutured to the end of the bowel.
2. A Y anastomosis of the ureters is constructed and sutured to the end of the bowel.
3. A head-to-tail ureteroureteral anastomosis is formed, which is then sutured to the end of the bowel.

The ureters are spatulated for 1.5 to 2 cm, and fine 5-0 PDS sutures are used for each anastomosis.

Figure 97-25. Bricker ureterointestinal anastomosis. A, The adventitia of the ureter is sutured to the serosa of the bowel. A small full-thickness serosal and mucosal plug is removed. Interrupted 5-0 polydioxanone sutures approximate the ureter to the full thickness of the mucosa and serosa. B, The anterior layer is completed by interrupted sutures placed through the adventitia of the ureter and the serosa of the small bowel.

For the first anastomosis, a fine suture is placed at the apex of each ureter with the knot tied to the outside. The posterior medial ureteral walls are sutured together, and the anterior lateral walls are sutured directly to the bowel with interrupted 5-0 PDS. Where the suture line of the end of the ureters comes to the bowel, a horizontal mattress suture is placed to make the anastomosis watertight. If a Y type of anastomosis is desired, after the posterior ureteral walls have been sutured together as described previously, the anterior walls of the ureters are sutured together, and the end of the composite anastomosis is sutured to the bowel. Again, where the suture lines meet the bowel, a horizontal mattress suture is placed so that the anastomosis is watertight. The head-to-tail anastomosis involves suturing the end of one ureter to the apex of the other. The posterior medial walls of the two ureters are approximated. The anterior lateral walls are sutured to the bowel.

The Wallace anastomosis has the lowest complication rate of any of the ureterointestinal anastomotic techniques. Incidence of stricture formation is approximately 3%, of deterioration of the upper tracts is about 4%, and of leakage is about 2% (see Table 97-4). The Wallace technique is not recommended for patients who have extensive carcinoma in situ or who have a high likelihood of recurrent tumor in the ureter. A recurrence of tumor at the anastomotic line in one ureter would block both ureters, causing uremia from bilateral obstruction.

Tunneled Small Bowel Anastomosis

The tunneled small bowel anastomosis method attempts to establish a nonrefluxing anastomosis by construction of a submucosal tunnel (Fig. 97-27) (Starr et al, 1975). Two 0.5-cm incisions are

Figure 97-26. Wallace ureterointestinal anastomosis. A, Both ureters are spatulated and laid adjacent to each other. B, The apex of one ureter is sutured to the apex of the other ureter with 5-0 polydioxanone sutures (PDS). The posterior medial walls of both ureters are then sutured together with interrupted or running 5-0 PDS, the knots tied to the outside. The lateral ureteral walls are then sutured to the intestine. C, A Y-type anastomosis is formed by completing the anterior row of the anterior lateral ureteral walls of the ureters as shown in B and then suturing the ends of the ureters directly to the intestine. D, The head-to-tail anastomosis involves suturing the apex of one ureter to the end of the other. The posterior medial walls are sewn together, and then the ends and lateral walls are sewn to the intestine.

made in the serosa on the antimesenteric border 2.5 cm apart at right angles to the long axis of the bowel. The seromuscular layer is then gently separated from the mucosa with a blunt hemostat. The ureter is pulled through one incision, a button of mucosa is removed over the other incision, and the ureter is spatulated and sutured to the mucosa with interrupted 5-0 PDS. The serosa is then closed with interrupted 4-0 silk, and the adventitia of the ureter is sutured at its entrance through the serosa of the bowel to the serosa.

Good results have been reported, but this technique has not been widely used. Therefore long-term follow-up is not available (Osman et al, 2004).

Split-Nipple Technique

The split-nipple technique attempts to establish a nonrefluxing anastomosis by using a nipple mechanism. It may be applied to either the small or large bowel. This technique was described by Griffiths and involves formation of a nipple in the ureter and implantation into the small bowel (Fig. 97-28) (Turner-Warwick and Ashken, 1967). A 0.5-cm longitudinal incision in the ureter is made, and the ureteral wall is turned back on itself, constructing a nipple at least twice as long as its width. The cuff is stabilized at the corners with sutures. A button of seromuscular and mucosal tissue is removed, and the ureter is then placed into the bowel such that it protrudes through the mucosa. The adventitia just proximal to

Figure 97-27. Tunneled small bowel anastomosis. A small transverse incision is made in the small bowel, and a second transverse incision 3 cm lateral to it is also made. The submucosal tunnel is made, a button of mucosa is removed, and the ureter is drawn through the tunnel and sutured directly to the mucosa. The rent in the serosa is closed, and an adventitial ureteral suture is placed and secured to the serosa at the ureter's entrance to the small bowel.

Figure 97-28. A and B, Split-nipple technique. The ureter is spatulated and turned back on itself, and the end of the ureter is secured to the adventitia of the ureter with interrupted 5-0 polydioxanone sutures.

the point where the ureter has been sewn to itself is sutured to the full thickness of the bowel wall with interrupted 5-0 PDS. The anastomosis is stented.

In one series, this type of anastomosis prevented reflux in more than 50% of the patients. In subsequent series, approximately 80% of patients had a nonrefluxing anastomosis with an acceptably low incidence of stenosis (see Table 97-4). There is a stricture rate of about 7% (De Carli et al, 1997).

Le Duc Technique

The Le Duc method establishes a nonrefluxing anastomosis by laying the ureter onto the interior of the bowel wall, eventually resulting in a submucosal tunnel when it is re-epithelialized (Fig. 97-29) (Le Duc et al, 1987). This technique has been used to prevent reflux in the ureter–small intestine anastomosis. Excellent exposure is required, and therefore the small bowel needs to be opened along its antimesenteric border for a length of approximately 5 cm. The mucosa is incised for a length of 3 cm beginning 2 cm proximal to the cut edge of the bowel. It is important to begin the mucosal tunnel away from the cut edge of the bowel to allow enough distal bowel for closure without jeopardizing the entrance point of the ureter. The ureter is then brought through the serosa at the most distal portion of the mucosal sulcus, laid in the trough, spatulated, and sutured to the proximal end of the sulcus with interrupted 5-0 PDS using the full thickness of ureteral wall and anchored to the muscularis and mucosal layers of the bowel. The mucosa of the sulcus of the bowel is then sutured to the adventitia of the ureter. The mucosa of the bowel should not be sutured over the ureter but rather to its lateral aspect. The idea is that the mucosa eventually grows over the top of the ureter. Where the ureter enters the small bowel, its adventitia is sutured to the bowel serosa with 4-0 silk sutures. Stents are placed in the ureter, and their passage must be unimpeded to ensure that there is no angulation. The bowel should be fixed to the body wall near the site of the ureteral implantation so that the ureters do not angulate.

The complication rate for this technique is relatively low, although the follow-up is also relatively short. Initial reports suggested that it carried with it an 87% incidence of maintaining an antireflux valve with a 5% incidence of stricture and a 2% incidence of leak (Schwaibold et al, 1998). A modification of the Le Duc technique was prompted by a 15% incidence of stricture when longer follow-up was available. With the modified technique, the stricture rate was 3% with 2½ years of follow-up. The technique involves construction of a 3-cm mucosal sulcus to the submucosa.

Figure 97-29. Le Duc ureterointestinal anastomosis. A, The small bowel is opened for approximately 4 to 5 cm. A longitudinal rent in the mucosa is made and the mucosa raised. B, At the distal end of the mucosal rent, a hole is made in the serosa, and the ureter is then drawn through. The entrance of the ureter through the serosa should be at least 2 cm proximal to the cut end of the bowel to allow sufficient bowel length to close the end. C, The ureter is spatulated and sutured to the mucosa and muscle layers. The mucosa is not reapproximated over the top of the ureter but rather sutured to the side of it.

The ureter is brought in the proximal sulcus transmurally and anchored to the serosa externally. The ureter is spatulated for 1.5 cm, and only the spatulated portion is sewn to the muscularis of the bowel. The proximal intraluminal ureter is not fixed to the bowel (see [Table 97-4](#)).

Hammock Anastomosis

The hammock anastomosis involves conjoining the ureters and implanting them into the small bowel in a nonrefluxing manner. The small bowel is closed at its proximal end, and three 10-cm longitudinal incisions separated by 1 to 2 mm are made through the seromuscular layer to the mucosa. These incisions are cross-hatched by multiple incisions. This serves as a hammock. The ureters are conjoined as in the Wallace technique and sutured to the intestinal mucosa. The ureters are buried by closing the intestinal wall over the top of them with seromuscular sutures of 3-0 polyglycolic acid suture ([Hirdes et al, 1988](#)).

With this technique, there is a 6% incidence of ureteroileal stenosis and approximately a 20% incidence of reflux. Follow-up, however, is relatively short.

Ureteral Dipping Technique

Described in 640 patients who underwent continent urinary diversion, the dipping technique is relatively simple to perform and has excellent success ([Wishahi et al, 2013](#)). Wishahi and colleagues form the neobladder, then make a small opening in the small bowel wall. The ureter is “dipped” approximately 1 cm into the bladder cavity, then secured to the seromuscular portion of the bowel. No mucosal anastomosis is performed, but the long-term success of renal preservation reported deserves further investigation.

Ureter–Small Bowel Anastomosis Using Serosal Compression of the Extramural Ureter as an Antireflux Mechanism

Primarily applicable to a continent diversion in which detubularized small bowel is used and an antireflux ureterointestinal anastomosis is desired, ureter–small bowel anastomosis involving serosal compression of the extramural ureter requires two segments of small bowel to be juxtaposed. The ureter is laid between the two small bowel serosal surfaces, which are sutured posterior and anterior to the extramural portion of the ureter. The technique is as follows.

The posterior wall of the extramural tunnel is composed of the two segments of small bowel sutured together with 3-0 silk ([Fig. 97-30A and B](#)). The two segments of small bowel are opened along their antimesenteric borders. The ureter is spatulated and sutured to the mucosal-seromuscular layer with 5-0 absorbable sutures. The edges of the opened small bowel are then reapproximated over the anterior ureter with absorbable sutures ([Fig. 97-30C](#)), thus making a serosal tunnel 4 cm in length. When the bowel is distended, it then applies pressure to the extramural ureter, thus preventing reflux ([Abol-Enein and Ghoneim, 1994](#)).

With an average of 3 years of follow-up, the anastomotic stricture rate is 4% and the rate of failure of the antireflux mechanism is 3% ([Abol-Enein and Ghoneim, 2001](#); [Turkolmez et al, 2004](#)).

Intestinal Antireflux Valves

Another technique for preventing reflux into the ureter involves construction of an antireflux mechanism with bowel distal to the ureterointestinal anastomosis. The ureter is sutured by the technique of either Bricker or Wallace (as described earlier) to the end of the bowel, and the bowel is used to make a one-way valve. Unlike with individual ureterointestinal antirefluxing anastomosis, when these valves fail or stenose, both kidneys are affected. Three basic types of antireflux mechanisms commonly used with the bowel are ileocecal intussusception, ileoileal intussusception, and ileal nipple valve placed into colon.

Intussuscepted Ileocecal Valve

The mesentery is cleaned from the ileum for a length of 8 cm beginning at the cecum and coursing proximally ([Fig. 97-31](#)). At least 5 cm of ileum proximal to the detached mesentery must be intact to ensure intestinal viability. Thus the ileum should not be transected less than 13 cm from the ileocecal junction. A No. 22 catheter is placed through the ileum into the cecum. The ileal serosa is scarified either by multiple cross-incisions with a knife or with the electrocautery unit. The 8-cm segment is intussuscepted over the catheter into the cecum. The intussuscepted ileum is secured to the cecal wall with 3-0 silk sutures placed circumferentially 2 mm apart.

The valve has a moderate tendency to fail because the intussusception has a significant chance of reduction. In one series, the antireflux mechanism remained intact in 55% of the patients during the long term ([Hensle and Burbige, 1985](#)). The intussusception may be made more secure by using a modification described by King. The mesentery is cleaned as described before. The cecum is opened along a taenia, and the ileum is intussuscepted over the catheter under direct vision. Where the intussusception lies adjacent to the cecal wall, mucosa of the intussuscepted ileum and the cecal mucosa adjacent to it are incised down to muscle. The muscles are sewn together with interrupted 3-0 chromic suture. Long-term follow-up in eight patients reveals maintenance of the antireflux valve in seven with the modified technique ([King, 1987](#); [Friedman et al, 1992](#)). The Mainz group advocates stapling the intussuscepted ileum to the ileocecal valve to prevent reduction. In their series, 82% of patients maintained valve competence; however, there was a 20% incidence of stone formation ([Wiesner et al, 2006](#)).

Intussuscepted Ileal Valve

The mesentery is cleaned from an 8-cm segment of ileal serosa ([Fig. 97-32](#)). There must be 5 cm of ileal mesentery proximal and distal to the cleared segment to ensure proper blood supply. The ureters are sewn to the proximal end of ileum. The distal end of ileum is opened along its antimesenteric border to within 2 to 3 cm of the cleared mesentery to provide adequate exposure and direct visualization of the intussuscepted segment. A Babcock clamp is placed into the lumen of the bowel, and a portion of bowel wall is grasped by invaginating it into the clamp with a finger. The ileal segment is intussuscepted by pulling on the Babcock clamp with gentle constant traction. If there is resistance, the mesentery is usually too bulky, and it must be defatted carefully before another attempt to intussuscept the segment. A 5-cm intussuscepted segment should protrude. The gastrointestinal stapler without the knife or the linear stapler, from which the distal five to eight staples have been removed, is used to secure the intussusception in place; three rows with the gastrointestinal stapler or four rows with the linear stapler are placed in quadrants. The staple size should be 4.8 mm. The proximal staples are important in securing the intussusception and preventing its reduction, whereas the distal staples are less effective and more likely to be exposed to urine and thus facilitate stone formation. It is for this reason that the distal staples are removed from the staple cartridge before it is placed in the stapler and before the intussusception is stapled. With the cautery unit, the mucosa of the intussusception is incised along its length. Adjacent to this incision, another is made in the mucosa of the ileum. The muscularis of both is exposed and sewn together with interrupted 3-0 chromic suture. The distal serosa is then sutured proximally to the serosa of the intussuscepted segment circumferentially with 3-0 nonabsorbable sutures. This is meant to secure the intussusception and to prevent its reduction with failure of the antireflux mechanism. The valve is successful in preventing reflux 90% of the time ([Kock et al, 1982](#); [Skinner et al, 1989](#)).

Because the intussuscepted nipple valve as an antireflux mechanism has resulted in a 10% complication rate (5% stone formation on the exposed staples, 4% stenosis, and 1% prolapse [[Stein et al, 1996a](#)]), modifications have been developed in an attempt to

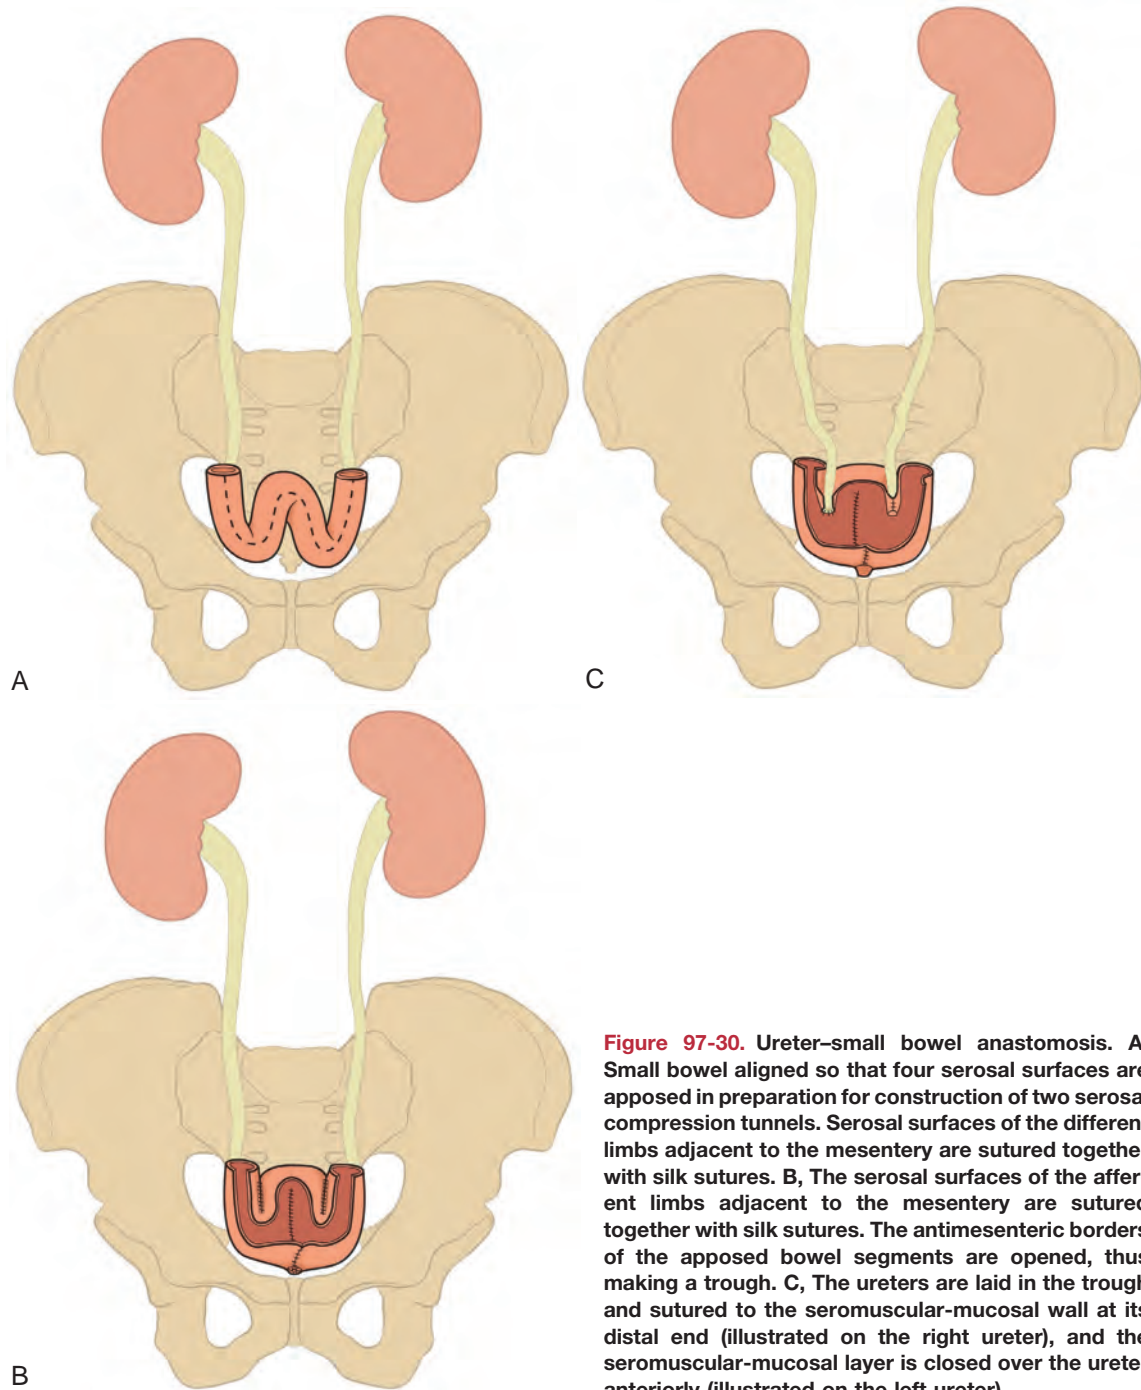

Figure 97-30. Ureter–small bowel anastomosis. **A,** Small bowel aligned so that four serosal surfaces are apposed in preparation for construction of two serosal compression tunnels. Serosal surfaces of the different limbs adjacent to the mesentery are sutured together with silk sutures. **B,** The serosal surfaces of the afferent limbs adjacent to the mesentery are sutured together with silk sutures. The antimesenteric borders of the apposed bowel segments are opened, thus making a trough. **C,** The ureters are laid in the trough and sutured to the seromuscular-mucosal wall at its distal end (illustrated on the right ureter), and the seromuscular-mucosal layer is closed over the ureter anteriorly (illustrated on the left ureter).

reduce these untoward outcomes. One such modification has been described by the University of Southern California group. An 8- to 10-cm isolated segment of ileum is tapered distally and laid between two segments of small bowel in which their serosal walls adjacent to the mesentery are sutured together. This serves as the posterior support for the isolated segment. The apposed bowel is opened along its antimesenteric border; lateral flaps are constructed adjacent to the segment and closed over its anterior aspect, thus making a serosal trough in which 4 cm of the segment of tapered ileum is positioned (Stein and Skinner, 2003). When the pouch is closed, a nipple valve is constructed. The concept is that as pressure in the pouch increases, the walls of the tapered nipple valve are compressed, thus preventing reflux. The authors call their modification a *T pouch*.

Nipple Valve

The simplest intestinal antireflux valve to make is the nipple valve with use of ileum (Fig. 97-33). The mesentery is cleared from the last 8 cm of the cut end of the ileum. The distal 6 cm of serosa is scarified by multiple cross-striations and then turned back on itself to form a nipple. The nipple should be at least 4 to 4.5 cm in length. The end of the inverted ileum is then sutured to itself with interrupted 4-0 PDS. An incision on the taenia large enough to accommodate the segment is made. A No. 22 catheter is placed through the segment, and its serosa is sutured to the colon serosa circumferentially with interrupted 3-0 silk sutures placed 2 mm apart. The long-term success rate for this type of valve is unknown but is comparable to tunneled anastomoses (Osman et al, 2004).

Figure 97-31. Ileocecal intussusception. A, An 8-cm segment of ileal mesentery is cleaned from the serosa beginning at the ileocecal junction. At least 5 cm of mesentery remains attached to the proximal ileum. An incision is made along a taenia at the level of the ileocecal valve. B, The ileum is intussuscepted over a 22-Fr catheter into the cecum under direct vision. The mucosa of the intussuscepted segment is incised, and the mucosa of the cecum adjacent to it is also incised. The muscle coats of both segments are sutured together. The serosa of the ileum is secured to the serosa of the cecum with interrupted 3-0 silk sutures placed circumferentially (not depicted).

Figure 97-32. Intussuscepted ileal nipple valve. An 8-cm length of ileal mesentery is cleaned from the serosa. The ileum distally is opened within 2 to 3 cm of the rent in the mesentery; a 5-cm length of ileum is intussuscepted and secured by placement of staples in quadrants. The ileal mucosa is incised adjacent to an incision in the intussuscepted segment, and the two muscle coats are sutured together with interrupted 3-0 chromic suture. The serosa of the intussuscepted segment is sutured circumferentially to the base of the ileum, into which the proximal segment is intussuscepted with interrupted silk suture.

Complications of Ureterointestinal Anastomoses

The complications that occur with ureterointestinal anastomoses include leakage, stricture, reflux in those anastomoses that were performed to prevent reflux, and pyelonephritis. In a review of the various types of procedures, it appears that of the colonic antirefluxing procedures, the Pagano technique offers the lowest incidence of stricture with an acceptable incidence of reflux. With

Figure 97-33. Nipple valve. Approximately 8 cm of mesentery are cleaned from the distal end of the ileum, and the serosa is scarified and then turned back on itself to form a nipple of approximately 4 cm in length. The end of the ileum is sutured to itself with interrupted 4-0 polydioxanone sutures (PDS). A rent is made in the colon through a taenia, and the nipple valve is placed through the rent and secured with circumferential interrupted 4-0 PDS through the full thickness of the colon and the seromuscular layer of the ileum.

respect to small bowel antireflux procedures, the Le Duc procedure and the ureterointestinal serosal apposition procedure seem to offer the lowest incidence of stricture with the highest success rates in preventing reflux. With respect to stricture formation and leakage, it appears the Wallace technique has the best results. In a comparison of the Bricker, the Wallace, and the nipple valve, however, in one series there was no difference in complication rate among any of the procedures. In another contemporary series the Wallace technique had the lowest incidence of stricture (Kouba et al, 2007). All had an incidence of approximately 29% of some form of obstruction in the long term (Mansson et al, 1979). In a more recent study, there appeared to be no difference between rate of reflux and stricture when a Bricker anastomosis was compared with a split-cuff nipple. The incidence of stricture was 7% for both types (De Carli et al, 1997).

Urinary Fistula

Urinary fistulas typically occur within the first 7 to 10 days postoperatively with an incidence of 3% to 9% (see Table 97-4) (De Nunzio et al, 2013; Loening et al, 1982). The incidence of urinary intestinal leak is markedly reduced by the use of soft Silastic stents (Mattei et al, 2008). A urinary intestinal leak may cause peri-ureteral fibrosis and scarring with subsequent stricture formation.

Stricture

In general, the antirefluxing techniques have a higher incidence of stricture. Patients are at risk for ureterointestinal strictures for the life of the anastomosis and must be observed on a scheduled periodic basis. A stricture has been reported to develop 13 years after the procedure (Shapiro et al, 1975). Ureteral strictures also occur away from the ureterointestinal anastomosis. This stricture is most common in the left ureter and is usually found as the ureter crosses over the aorta beneath the inferior mesenteric artery. It has been suggested that this occurs because of overly aggressive stripping of adventitia and angulation of the ureter at the inferior mesenteric artery.

Once a stricture has developed, various techniques may be used to rectify the situation. The most successful is re-exploration, with removal of the stenotic segment and reanastomosis of the ureter to the bowel by one of the aforementioned techniques. A number of

studies have compared open surgical correction of ureterointestinal anastomotic strictures with endourologic methods. In general, open repair has a success rate of approximately 75% at 3 years versus 15% for balloon dilation with similar follow-up (DiMarco et al, 2001). Open surgical methods may be morbid and difficult procedures. Endourologic procedures using balloon dilation have not proved to be durable, and therefore many surgeons have used either cold knife incisions or laser incisions. When several series involving use of endourologic methods are combined, there is a 50% to 60% success rate with 2 years of follow-up. Strictures occurring in less than 1 year from the original procedure, strictures 1.5 cm or longer, and left-sided strictures have less favorable outcomes with endourologic methods (Kramolowsky et al, 1987, 1988; Cornud et al, 1996; Laven et al, 2001; Poulakis et al, 2003). These data must be viewed with caution because longer follow-up usually results in additional recurrences. In selected patients, metallic stents have been used, which might be a reasonable approach in a patient with a limited life expectancy, thus avoiding a major open operation (Barbalias et al, 1998). In a study in which nonmalignant ureterointestinal strictures were stented, researchers reported that all patients were successfully treated with 2 years of follow-up; one patient developed a stone on the stent (Palascak et al, 2001).

Pyelonephritis

Acute pyelonephritis occurs both in the early postoperative period and during the long term. Its incidence is approximately 10% to 20% in patients diverted with ileal conduits and 9% in those diverted with antirefluxing colon conduits (see Table 97-3). These complications cause considerable morbidity and in fact are associated with significant mortality. In one series of intestinal segments in the urinary tract, 8 of 178 patients died of sepsis (Schmidt et al, 1973). That these complications may result in delayed mortality is indicated by the fact that 2 of 115 children and 3 of 127 adults died of septic complications 5 to 14 years after intestinal diversion (Pitts and Muecke, 1979). When sepsis is associated with decreasing renal function and uremia, the morbidity and mortality are markedly increased.

Table 97-4 summarizes the complications and success rates for the various types of anastomoses. The table is derived from composite reports in the literature in which specific anastomoses were described and from which the data could be accurately analyzed. Because of these two requirements, it is not possible to comment, for example, on the incidences of reflux or leakage among various anastomotic types inclusively. These complications can be minimized by adherence to the principles of ureterointestinal surgery discussed earlier.

RENAL DETERIORATION

The incidence of renal deterioration after conduit urinary intestinal diversion has varied from 10% to 74% (Madersbacher et al, 2003; Gilbert et al, 2013; Eisenberg et al, 2014). This variance is perhaps a result of the fact that many reports include both renal units that were abnormal and those that were normal before diversion. In analyzing abnormal renal units before diversion and documenting progressive disease, it is difficult to be sure whether the urinary diversion caused the progression or whether progression is caused by the intrinsic abnormality for which the diversion was constructed. When the incidence of renal deterioration is determined by comparing renal units that were normal before diversion and then deteriorated postoperatively, 18% of patients who have ileal conduits show progressive deterioration versus 13% who have nonrefluxing colon conduits (see Table 97-3). Twenty percent of patients with nonrefluxing continent ileocecal bladders show some evidence of deterioration of the upper tracts when they are observed during the long term (Benchekroun, 1987). This deterioration leads to a 10% incidence of azotemia in children with ileal conduits (Schwarz and Jeffs, 1975) and a 12% (5 of 41 patients) incidence of renal failure in patients with colon conduits

constructed for benign disease (Elder et al, 1979). There is significant and progressive deterioration in renal function in the majority of patients independent of the type of urinary diversion (Eisenberg et al, 2014).

The incidence rates for both sepsis and renal failure are greater in patients with ureterosigmoidostomy than in those with conduits. Sepsis and renal failure may occur either in the immediate postoperative period or many years later. The most common cause of death in patients who have had a ureterosigmoidostomy for more than 15 years is acquired renal disease (i.e., sepsis or renal failure). In this group of patients, approximately 10% to 22% die of these disorders (Zabbo and Kay, 1986), some as late as 27 years after diversion (Mesrobian et al, 1988). In patients with ileal conduits, about 6% ultimately die of renal failure (Richie, 1974).

Renal Function Necessary for Urinary Intestinal Diversion

The amount of renal function required to effectively blunt the reabsorption of urinary solutes by the intestinal segment and to prevent serious metabolic side effects depends on the type of urinary intestinal diversion constructed (i.e., the amount of bowel to be used and the length of time the urine is exposed to the intestinal mucosa). Thus a greater degree of renal function is necessary for retentive (continent) diversions than for short conduit diversions. In general, patients who have a glomerular filtration rate (GFR) on average above 40 mL/min tolerate a continent diversion reasonably well. Indeed, in one study, two groups of patients were analyzed: those with GFRs around 100 mL/min (range, 91 to 112) and those with GFRs around 55 mL/min (range, 36 to 69). Both seemed to tolerate the metabolic load well with a minimal development of metabolic acidosis. There was a slightly increased incidence of metabolic acidosis in the group with low GFR, as would be expected; however, in this group, distal tubule function was excellently maintained as demonstrated by ammonium chloride loading. This observation points out that GFR is not the sole determining factor that allows the body to manage intestinal diversion. Indeed, GFR is but one factor. Just as important is distal tubule function. This article confirms that when distal tubule function is normal and the GFR is above 40 mL/min, patients do extremely well (Kristjansson et al, 1997).

There are five components of renal function: renal blood flow, glomerular filtration, tubule transport, concentration and dilution, and glomerular permeability. Aspects of renal function that must be specifically addressed are GFR, best measured by inulin clearance; ability of the tubule to acidify, determined by ammonium chloride loading; concentrating ability, determined by water deprivation; and glomerular permeability, reflected by urine protein concentrations. In general, patients with normal urine protein content who have a serum creatinine concentration below 2.0 mg/dL do well with intestine interposed in the urinary tract. Serum cystatin C is a promising serum protein that reflects GFR more accurately than creatinine; however, its usefulness in urinary intestinal diversion has not yet been determined (Herget-Rosenthal et al, 2012; Inker et al, 2012). At a level of serum creatinine below 2 mg/dL, renal blood flow, GFR, tubule transport, and concentrating and diluting ability are relatively well preserved. In patients whose serum creatinine concentration exceeds 2 mg/dL and who are being considered for retentive diversion or in whom long segments of intestine will be used, a more detailed analysis of renal function is necessary. If the patient can achieve a urine pH of 5.8 or less after an ammonium chloride load, has a urine osmolality of 600 mOsm/kg or higher in response to water deprivation, has a GFR that exceeds 35 mL/min, and has minimal protein in the urine, the patient may be considered for a retentive diversion.

URINARY DIVERSION

This section deals with specific types of conduit urinary diversions. Fundamentally, there are two types of conduits: (1) those using the

small bowel, which includes the jejunum or ileum, and (2) those in which a portion of large bowel is used. Conduits made of stomach have been described but are rarely indicated and may carry with them difficult problems of stomal maintenance. Their construction is not discussed here. Each type of conduit has specific indications and advantages, and for each there are specific complications. Some complications, however, are similar among all types. The indications for a conduit are the need for urinary diversion: after a cystectomy; because of a diseased bladder; before transplantation in a patient who has a bladder that cannot adequately receive the transplant ureter; and for dysfunctional bladders that result in persistent bleeding, obstructed ureters, poor compliance with upper tract deterioration, and inadequate storage with total urinary incontinence.

Preparation

Regardless of whether small or large bowel is used for the conduit, although subject to debate as noted previously, it is my preference that all patients have a bowel preparation as outlined earlier. The reason for this is that large segments of bowel are exposed to the urinary tract and in many cases require detubularization, thus exposing the abdominal cavity to a large amount of solid fecal material if the bowel is unprepared. The specific types of ureteroileointestinal anastomosis and stomal construction and their complications are also described in previous sections. This section describes features that are unique to the construction of the conduit. The complications cited for each conduit also depend on the length of follow-up and the concomitant procedure performed.

Ileal Conduit

In the ileal conduit procedure, a portion of distal ileum is chosen. It is the simplest type of conduit diversion to perform and is associated with the fewest intraoperative and immediate postoperative complications. It is not advisable to use ileum for a conduit in patients with a short bowel syndrome, in patients with inflammatory small bowel disease, and in those whose ileum has received extensive irradiation, often as a consequence of prior radiation therapy for a pelvic malignant neoplasm.

Procedure

A segment 10 to 15 cm in length is selected 10 to 15 cm from the ileocecal valve. The cecum and ileal appendage (i.e., that portion of the distal ileum fixed to the retroperitoneum) are mobilized. The ileal mesentery is transilluminated, and a major arcade to the segment selected identified. With a mosquito clamp, the mesentery immediately beneath the bowel is penetrated, and the bowel is encircled with a vessel loop. An area at the base of the mesentery that is to one side of the feeding vessel is selected, and a second vessel loop is placed through the mesentery. At this juncture, the peritoneum overlying both sides of the mesentery is incised from bowel vessel loop to the base of mesentery vessel loop. With mosquito clamps, the tissue is clamped, severed, and tied with 4-0 silk. A portion of mesentery 2 cm in length is cleaned away from the bowel beneath the mesenteric incision. This procedure is repeated at the other end of the selected segment. The base of the mesentery should be as wide as possible and the mesenteric windows not excessive (in general about 5 cm in length) to prevent ischemia of the segment. Allen clamps are placed across the bowel in an angled fashion such that the antimesenteric portion is shorter than the mesenteric portion. (Some prefer to transect the bowel with an anastomotic stapler.) Thus a triangular piece of bowel is removed and discarded.

The isolated ileal segment is placed caudad, and an ileoileostomy is performed as described earlier (Fig. 97-34). The mesenteric window of the ileoileostomy is closed with interrupted 3-0 silk sutures. The isolated segment is then flushed with copious amounts of saline until the irrigant is clear, at which point the ureters are brought out the retroperitoneum in the right lower quadrant. To

Figure 97-34. The isolated segment of ileum is placed caudal to the ileoileostomy. An incision on the mesentery of the isolated segment 1 cm from the bowel wall straightens the end. In general, this is not necessary unless the mesentery is excessively bulky.

accomplish this, the left ureter must be brought over the great vessels and posterior to the sigmoid mesentery to the rent in the posterior peritoneum. This may be done by mobilizing the cecum cephalad to identify the right ureter. The left ureter may be identified by incising the line of Toldt of the left descending colon (Fig. 97-35). This dissection allows anastomosis of the ileal segment as proximally as needed to the ureter. Indeed, the ileum may be anastomosed directly to the renal pelvis on both sides if necessary (see Fig. 97-35C). After a cystectomy, the ureters are identified caudad to the iliac vessels and may be conveniently traced cephalad similar to the previous description. The ureteroileal anastomoses are performed as described previously. These anastomoses are stented.

A convenient method of introducing the stent through the loop to the opening in the bowel is illustrated in Figure 97-36. The base of the conduit is fixed to the retroperitoneum in the right lower quadrant by suturing the posterior peritoneum to the conduit, thus effectively retroperitonealizing the ureteroileal anastomosis. The stoma is made as described previously. I prefer to suture the loop segment to the lateral peritoneal wall, thus obviating any chance of herniating small bowel lateral to the conduit. Many prefer to bring the segment directly to the anterior abdominal wall, however, thus allowing bowel to descend caudad on either side of the loop.

Robotic surgical approaches have been described but should be attempted only by the most experienced surgeons (Tyrizis et al, 2012).

Complications

Early and late postoperative complications are listed in Table 97-5. It is difficult to clearly ascribe these complications solely to construction of the conduit because many are reported in patients undergoing a cystectomy as well. These incidences in Table 97-5 are therefore expected to reflect the high end of the spectrum. Bleeding may occur from either the stoma or the conduit itself. Approximately 10% of patients have stomal bleeding. In 4%, it originates from the loop beneath the fascia (Delgado and Muecke, 1973). Bleeding that is extremely difficult to manage may be a result of cirrhosis and varices. In this situation, life-threatening bleeding from the conduit may occur. To stop the bleeding, portal decompression may be required (Chavez et al, 1994). A less morbid method involves percutaneous transhepatic portal shunt or transhepatic angiography with embolization (Lashley et al, 1997; Medina et al, 1998). Indeed, this has been successful in several reported cases. Complications not listed include hypertension, renal failure, decreased renal function, and death. These complications

Figure 97-35. A, The cecum and root of the mesentery are incised. By blunt dissection, the cecum, ascending colon, and small bowel are mobilized cephalad. B, The right and left ureters are identified. The left ureter is more easily identified by mobilizing the left colon. C, The left colon is mobilized by incising the line of Toldt. This degree of mobilization allows anastomosis of the ileal segment to as proximal a position to the ureter as needed. This figure depicts a left renal pelvic and right ureterointestinal anastomosis.

Figure 97-36. The ureterointestinal anastomoses should be stented with soft Silastic stents. These stents may be conveniently introduced with a Yankauer suction instrument from which the tip has been removed. The suction instrument is introduced by way of the distal end of the segment to the desired location of the ureteral anastomosis. When one cuts down on the Yankauer tip, its end protrudes through the bowel at the desired site. The stent is threaded through the suction instrument, and the instrument is removed.

in large part depend on the concomitant procedure performed, the length of follow-up, and the status of the kidneys before diversion. During the long term (20 years), 7% of patients have renal failure requiring dialysis, and 60% show deterioration of the upper tracts (Koch et al, 1992). After salvage cystectomy, complications are increased so that approximately one third of patients have one of the early complications (Abratt et al, 1993). Also, the complication rate is increased in patients in whom an intestinal segment is used who require renal transplantation (Nguyen et al, 1990).

One should be cautious in identifying duplex ureters. A failure to identify a second ureter on one side results in intraperitoneal urine leak and can cause excessive morbidity (Evans et al, 1994). The duplex ureters may be dealt with by implanting them separately if they are of sufficient caliber, or they may be spatulated, sewn together, and then implanted into the ileal conduit as a single unit (Fig. 97-37).

Jejunal Conduit

The jejunum has the largest diameter of the small bowel and the longest mesentery. In general, jejunal conduits have not had a high

TABLE 97-5 Complications: Ileal Conduit*

	EARLY	LATE
Urine leak	2% (9/356)	
Bowel leak		
Sepsis	3% (7/230)	3% (4/142)
Acute pyelonephritis	3% (21/700)	18% (133/726)

rate of acceptance because of perceived electrolyte abnormalities. A more recent report of patients, most of whom were observed for more than 5 years, has shown that the bulk of electrolyte problems are minor; only about 4% in that series had severe hyponatremic metabolic acidosis. Renal calculi (12%), parastomal hernia (6%), and pyelonephritis (4%) constituted the majority of the remaining complications (Fontaine et al, 1997). The advantage of using the jejunum is that it avoids irradiated bowel and ureter. It is difficult to make a case for the jejunal conduit except in circumstances in which it is inadvisable to use either colon or ileum. However, this series does point out that when necessary, one can successfully use jejunum as a conduit. This might occur in patients who have extensive irradiation that involves the ileum, those with severe adhesions of the ileum and absence of the large bowel, and those who have an absent colon with inflammatory disease of the distal small bowel. **The contraindications to its use are severe bowel nutritional disorders and the presence of another acceptable segment.**

Procedure

The procedure is similar to that for an ileal conduit. A 10- to 15-cm segment of jejunum is isolated 15 to 25 cm from the ligament of Treitz as described for the ileal conduit. One should plan for the stoma to be in the upper quadrant, typically the left upper quadrant. The remainder of the technique is as described for the ileal conduit.

Complications

The early and long-term complications are similar to those listed for ileal conduit except that the electrolyte abnormality is a hyperkalemic, hyponatremic metabolic acidosis instead of the hyperchloremic metabolic acidosis of ileal diversion (Table 97-6). The treatment of the jejunal syndrome consists of administration of sodium chloride and sodium bicarbonate. Thiazide diuretics may also be used and are helpful in allaying the hyperkalemia (Hasan et al, 1994).

Colon Conduit

Three types of colon conduits are commonly used: transverse, sigmoid, and ileocecal. Each has specific indications with advantages and disadvantages.

The transverse colon is used when one wants to be sure that the segment of conduit used has not been irradiated in individuals who have received extensive pelvic irradiation. It is also an excellent segment when an intestinal pyelostomy needs to be performed. The sigmoid conduit is a good choice in patients undergoing a pelvic exenteration who will have a colostomy. Thus no bowel anastomosis needs to be made. It also allows non-refluxing submucosal reimplantation and provides for an easily placed left-sided stoma when that is desirable.

Figure 97-37. Intravenous urogram 6 days postoperatively in a patient who had bilateral duplex ureters. The ureters on each side were spatulated, sewn together, and anastomosed to the ileum.

The use of sigmoid colon is contraindicated with disease of this segment or when the hypogastric arteries have been ligated and the rectum has been left in situ. The latter circumstance may result in sloughing of the rectum or its mucosa because its blood supply of necessity is interrupted. It is also unwise to use this segment in individuals with extensive pelvic irradiation because it has probably been included in the radiation fields.

An ileocecal conduit has the advantage of providing a long segment of ileum when long segments of ureter need replacement, as well as the advantage of providing colon for the stoma. It is also used in situations in which free reflux of urine from the conduit to the upper tracts is thought to be undesirable. Contraindications to the use of transverse, sigmoid, and ileocecal conduits include the presence of inflammatory large bowel disease and severe chronic diarrhea.

Procedure

Transverse Colon. The segment may be isolated on the right or middle colic arteries, most commonly the latter (Fig. 97-38). The gastrocolic ligament is taken down, and the omentum is dissected from the portion of colon that is to be isolated. The splenic and hepatic flexures should be mobilized next. The proper length of segment is determined by taking into consideration the desired location of the stoma and the length of available ureters. In general, a length of 15 cm is sufficient. It is important not to isolate a segment that is too short and therefore incapable of reaching the retroperitoneum in such a position that a tension-free ureterocolonic anastomosis may be performed and retroperitonealized. The segment is isolated between bowel clamps, and a two-layer colocolostomy or stapled anastomosis is performed as outlined earlier. The segment is placed caudad to the anastomosis. If a colopyelostomy is to be performed, the segment should be placed cephalad to the bowel anastomosis. The isolated segment is irrigated with copious amounts of saline until the effluent is clear. The proximal end is closed with a running Connell suture of 3-0 chromic and a second layer of Lambert sutures of 3-0 silk. The ureterocolic anastomoses are then performed (see earlier), and the end is anchored to the retroperitoneum close to the midline. The stoma is usually placed in the right upper quadrant but may be placed anywhere in the abdomen if indicated.

Sigmoid Colon. The sigmoid colon is mobilized by incising its peritoneal attachments and the line of Toldt along the descending colon. The segment is isolated on the sigmoid vessels and placed lateral to the sigmoid colon (Fig. 97-39). The anastomosis of the sigmoid colon and ureterocolic anastomosis are as described for the transverse colon.

Figure 97-38. Transverse colon conduit may be based on right colic or middle colic arteries (depicted). (From Hinman F Jr. *Atlas of urologic surgery*. Philadelphia: Saunders; 1989.)

Ileocecal Conduit. The ileocecal conduit is based on the terminal branches of the superior mesenteric artery (i.e., ileocecal artery). The segment is placed caudad, and an ileum–ascending colon anastomosis is performed as described previously. The stoma is placed in the right lower quadrant. The ileocecal valve may be reinforced to ensure prevention of reflux. This is described earlier (see Fig. 97-31). For the ureterointestinal anastomoses, also see the earlier description.

Complications

Early and late complications after a transverse colon (Beckley et al, 1982; Schmidt et al, 1985; Ravi et al, 1994), sigmoid, or ileocecal conduit are listed in Tables 97-7 to 97-9. As is true for the small bowel, complications not listed including death, renal failure, and renal deterioration depend on the concomitant procedure performed and the length of follow-up. It is interesting to note that early reports suggested a lower incidence of renal deterioration with colon conduits, but some recent series suggest that the incidence of these complications is about the same. However, there continue to be proponents of the colon conduit because in the long term the apparent incidence of pyelonephritis is 7.6% and of preservation of the upper tracts is 78% (Stein et al, 1996b).

Complications of the ileocecal conduit in one reported series occurred in 21% of patients (Matsuura et al, 1991). In this series, complications of the ileal conduit were compared with those of the ileocecal conduit, and there appeared to be no difference in the frequency of early and late postoperative complications. Early complications included urinary leakage, bowel obstruction, fecal leakage, acute renal failure, fulminant hepatitis, pneumonia, gastrointestinal bleeding, hemorrhage, perforation of ileum, heart failure, and wound dehiscence. Late complications included stomal prolapse, acute pyelonephritis, bowel obstruction, urinary stones, parastomal hernia, incisional hernia, stomal stenosis, and fecal leakage. There was no difference in the incidence of deterioration of the upper tracts with either form of diversion. Of some note is that at high pressures, a large portion of the ileocecal conduits experienced reflux. At low pressures, however, there was minimal or no reflux. Whenever a portion of colon is used for a conduit, chronic diarrhea may be a consequence.

Ileal Vesicostomy

An ileal vesicostomy uses spatulated ileum and a generous transverse cystostomy to decompress the bladder and to allow an appliance to be used on the abdomen. This procedure is particularly well suited to spinal cord injury patients or those with significant neurologic disease. The concept is that patients with a neurogenic bladder have an easier job of caring for themselves with an abdominal stoma. Patients who are particularly good candidates are those with significant detrusor–external sphincter dyssynergia. Those who have detrusor hyperreflexia, particularly women, may have an increased incidence of incontinence. The complications of the procedure include urethral incontinence requiring closure of the urethra in 20% of patients, stomal stenosis, and bladder and renal calculi.

The procedure is performed by spatulating an ileal segment and performing a generous transverse cystostomy. The spatulated ileum is sutured to the bladder with absorbable suture, and the distal segment is brought to the abdominal wall by fashioning a rosebud stoma. This results theoretically in a low-pressure reservoir. Its appeal is that if indicated at a later date, the patient's anatomy can be converted back to normal (Mutchnik et al, 1997; Atan et al, 1999).

Management Common to All Conduits

All anastomoses are stented with Silastic stents. A convenient method for introducing the stents through the conduit and into the ureter is illustrated in Figure 97-36. They are removed individually on the fourth to sixth postoperative days. If there is no

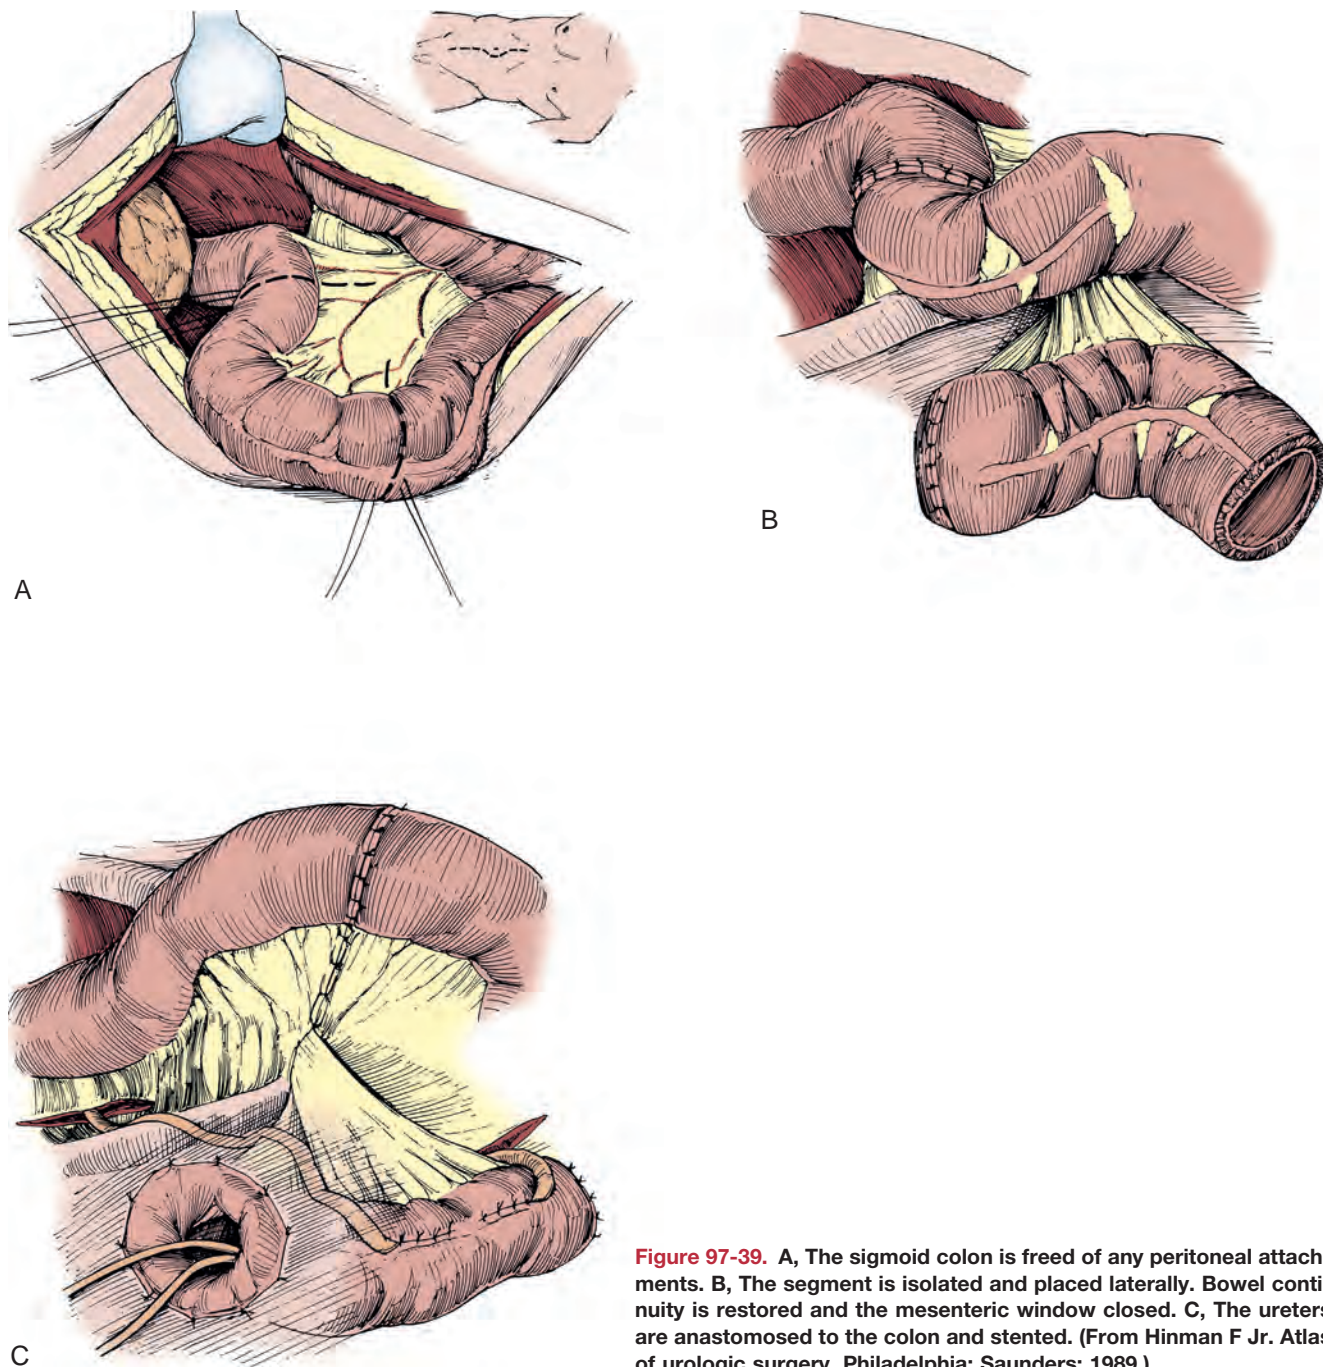

Figure 97-39. A, The sigmoid colon is freed of any peritoneal attachments. B, The segment is isolated and placed laterally. Bowel continuity is restored and the mesenteric window closed. C, The ureters are anastomosed to the colon and stented. (From Hinman F Jr. *Atlas of urologic surgery*. Philadelphia: Saunders; 1989.)

increase in drainage, the Jackson-Pratt closed-suction drain is removed. **All conduits are retroperitonealized**, with the uretero-intestinal anastomosis being placed in the retroperitoneum. This may be accomplished by suturing the posterior peritoneum to the serosa of the conduit above the ureterointestinal anastomosis. A drain may then be laid into the retroperitoneum. I prefer to drain the ureterointestinal anastomosis with a Jackson-Pratt or Blake closed-suction drain laid in the retroperitoneum 3 to 4 cm away from the anastomosis. The peritoneal cavity should not be drained.

All patients are given nothing by mouth until bowel function has returned. A progressive diet is instituted after confirmation of bowel activity. It has been my practice to use NGT decompression in all patients having a bowel anastomosis. In reported surgical series, it is clear that there are advantages and disadvantages of NGT decompression after intestinal surgery. Without its use, vomiting is more common. With its use, pulmonary complications are more

frequent. For patients with severe respiratory disease, consideration should be given to performing a gastrostomy. All patients have sequential compression boots applied as prophylaxis for pulmonary embolus. I have not used heparin or warfarin prophylaxis in this group of patients.

METABOLIC AND NEUROMECHANICAL PROBLEMS OF URINARY INTESTINAL DIVERSION

Problems that result from interposition of intestine in the urinary tract may be conveniently divided into three areas for the purposes of discussion: metabolic, neuromechanical, and technical-surgical. Metabolic complications are the result of altered solute reabsorption by the intestine of the urine that it contains. Neuromechanical aspects involve the configuration of the gut, which affects storage volume and contraction of the intestine that may lead to difficulties

TABLE 97-7 Complications: Transverse Colon Conduit*

	EARLY	LATE
Urine leak	8% (11/137)	8% (2/25)
Acute pyelonephritis		11% (8/75)
Wound infection	5% (5/92)	
Wound dehiscence	7% (8/109)	
Abscess		5% (3/62)
Prolonged ileus	6% (2/30)	
Ureteral stricture	6% (5/84)	17% (37/215)
Bowel obstruction	3% (1/30)	2% (2/109)
Parastomal hernia		4% (5/114)
Stones		11% (11/98)
Enterocutaneous fistula		2% (1/62)
Stomal stenosis		2% (1/62)
Stomal prolapse		11% (6/56)
Metabolic acidosis		12% (3/26)

*Incidence as a percentage of the total number of reported cases from the literature. Numbers in parentheses represent the number of cases from which the percentage is derived.

TABLE 97-8 Complications: Sigmoid Conduit*

	EARLY	LATE
Urine leak	1% (1/70)	
Wound infection	1% (1/70)	
Wound dehiscence	1% (1/70)	
Acute pyelonephritis		7% (5/70)
Bowel obstruction		6% (4/70)
Ureteral stricture		9% (6/70)
Stones		4% (3/70)
Parastomal hernia		3% (2/70)
Stomal stenosis		3% (2/70)

*Incidence as a percentage of the total number of reported cases from the literature. Numbers in parentheses represent the number of cases from which the percentage is derived.

TABLE 97-9 Complications: Ileocecal Conduit*

	EARLY	LATE
Urine leak	6% (9/147)	
Bowel leak	3% (5/147)	
Gastrointestinal bleeding	1% (1/147)	
Wound dehiscence	7% (11/147)	
Acute pyelonephritis		14% (20/147)
Bowel obstruction	3% (5/147)	10% (14/147)
Stomal prolapse		16% (24/147)
Parastomal hernia		5% (7/147)
Stomal stenosis		2% (3/147)
Stones		5% (8/147)
Fecal fistula		2% (3/147)

*Incidence as a percentage of the total number of reported cases from the literature. Numbers in parentheses represent the number of cases from which the percentage is derived.

in storage. Finally, technical-surgical complications involve aspects of the procedure that result in surgical morbidity; these have been discussed after each section on the technical aspects of urinary intestinal diversion. The following is a discussion of metabolic and neuromechanical problems.

Metabolic Complications

Metabolic complications include electrolyte abnormalities, altered sensorium, abnormal drug metabolism, osteomalacia, growth retardation, persistent and recurrent infections, formation of renal and reservoir calculi, problems ensuing from removal of portions of the gut from the intestinal tract, and development of urothelial or intestinal cancer. Many of these complications are a consequence of altered solute absorption across the intestinal segment. The factors that influence the amount of solute and type of absorption are the segment of bowel used, the surface area of the bowel, the amount of time the urine is exposed to the bowel, the concentration of solutes in the urine, the renal function, and the pH of the fluid.

Electrolyte Abnormalities

Serum electrolyte complications and the type of electrolyte abnormalities that occur are different, depending on the segment of bowel used. If stomach is used, a hypochloremic metabolic alkalosis may occur. If jejunum is the segment used, hyponatremia, hyperkalemia, and metabolic acidosis occur. If the ileum or colon is used, a hyperchloremic metabolic acidosis ensues. Other electrolyte abnormalities that have been described include hypokalemia, hypomagnesemia, hypocalcemia, hyperammonemia, and elevated blood urea nitrogen and creatinine. Specific abnormalities for each segment of intestine are detailed.

When stomach is used, a hypochloremic, hypokalemic metabolic alkalosis may ensue. In general, this is not a significant problem unless the patient has concomitant renal failure, in which case there is a significant impairment of bicarbonate excretion or the patient is significantly dehydrated (Kurztrock et al, 1998). The metabolic alkalosis on occasion can be severe and life-threatening (syndrome of severe metabolic alkalosis) (Table 97-10). This syndrome has been reported in patients with normal renal function. When it is fully manifested, lethargy, respiratory insufficiency, seizures, and ventricular arrhythmias may occur (Gosalbez et al, 1993). These symptoms are usually preceded by vomiting resulting in dehydration. A pronounced hypochloremic, hypokalemic metabolic alkalosis ensues. Patients are usually successfully treated with an H₂ blocker to reduce proton secretion by the gastric segment and rehydration. In life-threatening circumstances, arginine hydrochloride infusion has been used to rapidly restore acid-base balance. On occasion, when H₂ blockers are ineffective, the proton pump blocker omeprazole has been successfully used. Rarely, omeprazole is ineffective, and if the life-threatening metabolic alkalosis persists, the gastric segment must be removed (Gosalbez et al, 1993).

The role of the serum concentration of gastrin appears pivotal in the syndrome. In the severe cases that have been reported, there is typically an elevated serum gastrin level. Serum gastrin levels are significantly correlated with systemic bicarbonate concentration in gastrectomy patients; the greater the gastrin level, the more severe the metabolic alkalosis (Tanrikut and McDougal, 2004). When volume depletion, hypochloremia, and hypokalemia result from vomiting in those who normally have elevated circulating gastrin levels and a persisting long-standing metabolic alkalosis, the patient is at greater risk for development of the syndrome of severe metabolic alkalosis and manifestation of the symptoms outlined previously. Thus, persistent loss of protons from the gastric-augmented bladder with net addition of bicarbonate to the systemic circulation, alteration of normal homeostatic mechanisms for acute changes in acid-base balance, and impaired ability of even a normal kidney to excrete bicarbonate in the face of hypochloremia, hypokalemia, and increased circulating aldosterone levels (because of the dehydration) create a vicious circle in which normal homeostatic mechanisms are circumvented. Indeed, elevated aldosterone levels have been reported in this syndrome (Gosalbez et al, 1993). Hypokalemia, hypochloremia, and increased aldosterone levels impair the kidney's ability to excrete excess bicarbonate. These perturbations coupled with a continued addition of bicarbonate from

TABLE 97-10 Syndromes of Electrolyte Disturbances in Patients in Whom Bowel Is Interposed in the Urinary Tract

SYNDROME	SEGMENT	SYMPTOMS	ASSOCIATED ABNORMALITIES
Syndrome of severe metabolic alkalosis	Stomach	Lethargy, muscle weakness, respiratory insufficiency, seizures, ventricular arrhythmia	Elevated aldosterone, hypochloremia, hypokalemia
Syndrome of hyperkalemia, hypochloremia, metabolic acidosis	Jejunum	Lethargy, nausea, vomiting, dehydration, muscle weakness	Elevated renin, angiotensin
Syndrome of hyperchloremia, metabolic acidosis	Ileum, colon	Fatigue, anorexia, lethargy, weakness	Total-body potassium depletion, hypocalcemia

Figure 97-40. Sigmoid relationship of serum gastrin level to serum bicarbonate. Notice that over the physiologic range of normal gastrin levels, 10 to 120 ng/L, there is little change in serum bicarbonate. However, at levels of serum gastrin in excess of 120 ng/L, small changes in serum gastrin levels result in large changes in serum bicarbonate.

the gastric segment produce the extreme electrolyte abnormalities noted in the patients described. In view of the sigmoid correlation of serum bicarbonate to gastrin levels in patients with gastric segments in the urinary tract, patients at greatest risk for development of the syndrome of severe metabolic alkalosis are those whose serum gastrin concentrations exceed 120 ng/L because on this portion of the curve, small additional increments in gastrin concentration result in large increases in serum bicarbonate (Fig. 97-40). On the other hand, patients with serum gastrin concentrations below 100 ng/L can have significant increases in gastrin levels with little change in serum bicarbonate. Failure to properly empty the diversion with overdistention of the gastric segment would be expected to increase the serum gastrin level because stretch is a stimulus for gastrin release. For those who have either an elevated resting gastrin level in excess of 120 ng/L or impaired renal function, both patient and physician should be made aware of the consequences of dehydration and distention of the segment.

Electrolyte disorders that occur when jejunum is used for urinary intestinal diversion, particularly when proximal jejunum is used, include hyponatremia, hypochloremia, hyperkalemia, azotemia, and acidosis (see Table 97-10). These disorders result from an increased secretion of sodium and chloride with an increased reabsorption of potassium and hydrogen ions. This excessive loss of sodium chloride carries with it water, and thus the patient becomes dehydrated. The dehydration results in hypovolemia, which increases renin secretion and thereby aldosterone production (Golimbu and Morales, 1975). Aldosterone production may also be stimulated by hyperkalemia. The high levels of renin-aldosterone facilitate sodium reabsorption by the kidney and

potassium loss, which produce a urine low in sodium content and high in potassium. This, when presented to the jejunum, results in a favorable concentration gradient for loss of sodium by the jejunum and increased reabsorption of potassium, thus perpetuating the abnormalities.

These electrolyte abnormalities result in lethargy, nausea, vomiting, dehydration, muscle weakness, and elevated temperature. If the abnormalities are allowed to persist, the patient may become moribund and finally die. This syndrome may be exacerbated by administration of hyperalimentation solutions. The mechanism by which hyperalimentation solutions exacerbate this syndrome in patients with jejunal intestine interposed in the urinary tract is unclear (Bonnheim et al, 1984). The severity of the syndrome depends on the location of the segment of jejunum that is used. The more proximal the segment, the more likely the syndrome is to develop. Its incidence varies from a low of 25% (Klein et al, 1986) to the majority of patients demonstrating significant abnormalities. Severe abnormalities may occur in as few as 4% when short segments are used (Fontaine et al, 1997). Treatment of the disorder is rehydration with sodium chloride and correction of the acidosis with sodium bicarbonate. Provided that renal function is normal, the hyperkalemia is corrected by renal secretion. On occasion, a diuretic may be helpful to correct the hyperkalemia. After restoration of normal electrolyte balance, long-term therapy involves oral supplements with sodium chloride. A thiazide diuretic has also been useful in selected patients to control hyperkalemia in the long term (Hasan et al, 1994).

The electrolyte abnormality that occurs with the ileum and colon is hyperchloremic metabolic acidosis (see Table 97-10). This acidosis occurs to some degree in most patients who have ileum or colon interposed in the urinary tract but is usually of a minor degree. Its clinical significance when it is of a minor degree at this time is unknown. Hyperchloremic acidosis has been reported with a frequency of 68% of patients (19 of 28 patients; 10 of the 19 cases were severe enough to require treatment) with ileal conduits (Castro and Ram, 1970). In another study, 70% of patients with ileal conduits observed for 4 years or longer had a decreased serum bicarbonate concentration (Malek et al, 1971). A more current study places the incidence at about 25% (Nieuwenhuijzen et al, 2008) with about 4% requiring hospitalization for correction (Studer et al, 2006). Severe electrolyte disturbances occur to a much lesser degree. It has been reported to be a major problem in 18% of patients (8 of 45) with intestinal cystoplasties (Whitmore and Gittes, 1983), in 10% of patients (17 of 178) with ileal conduits (Schmidt et al, 1973), and in 80% of patients (112 of 141) with ureterosigmoidostomies (Ferris and Odel, 1950). In continent diversions involving either ileum and cecum or cecum alone, most patients have an elevated serum chloride and depressed serum bicarbonate (Ashken, 1987; McDougal et al, 1989). Sixty-five percent of patients with Mainz pouches require alkali therapy to maintain a normal acid-base balance (Thuroff et al, 1987). Early reports of patients with continent diversions made of ileum note a much lower incidence of electrolyte problems, in the range of 10% to 15% (see Table 97-3) (Allen et al, 1985; Boyd et al, 1989). Symptoms in those in whom the syndrome is severe include easy fatigability, anorexia, weight loss, polydipsia, and lethargy.

Those with ureterosigmoidostomies also have an exacerbation of diarrhea.

These electrolyte abnormalities, if significant and allowed to persist, result in major metabolic abnormalities, to be discussed subsequently. In and of themselves, however, they may be lethal because severe electrolyte abnormalities have contributed to death of patients (Heidler et al, 1979).

The mechanism of hyperchloremic metabolic acidosis is a result of the ionized transport of ammonium. Ammonium substitutes for sodium in the $\text{Na}^+\text{-H}^+$ antiport. The exchange of the weak acid NH_4 for a proton is coupled with the exchange of bicarbonate for chloride. Thus ammonium chloride is absorbed across the lumen into the blood in exchange for carbonic acid (i.e., CO_2 and water). Ammonium may also gain entry to the blood from bowel lumen through potassium channels (McDougal et al, 1995).

The treatment of hyperchloremic metabolic acidosis involves administration of alkalinizing agents or blockers of chloride transport. Alkalinization with oral sodium bicarbonate is effective in restoring normal acid-base balance. Oral administration of bicarbonate may not be tolerated particularly well, however, because it can produce considerable intestinal gas. An effective alternative is sodium citrate and citric acid solution (Bicitra or Shohl solution) used together; however, many patients do not care for the taste. Potassium citrate, sodium citrate, and citric acid solution (Polycitra) may be used instead if excessive sodium administration is a problem because of cardiac or renal disease and if potassium supplementation is desirable or at least not harmful. In patients in whom persistent hyperchloremic metabolic acidosis occurs and in whom excessive sodium loads are undesirable, chlorpromazine or nicotinic acid may be used to limit the degree of the acidosis. These agents used alone do not correct the acidosis in humans, but they limit its development and thus reduce the need for alkalinizing agents. Chlorpromazine and nicotinic acid inhibit cyclic adenosine monophosphate and thereby impede chloride transport. Chlorpromazine may be given at a dose of 25 mg three times a day. On occasion, as much as 50 mg three times a day may be necessary, but at such doses, side effects are not uncommon. Chlorpromazine should be used with care in adults because there are many untoward side effects including tardive dyskinesia. Nicotinic acid may be given at a dose of 400 mg three or four times a day. The drug should not be used in patients with peptic ulcer disease or significant hepatic insufficiency. Side effects that may be observed include exacerbation of liver dysfunction, exacerbation of peptic ulcer disease, headaches, and double vision. Flushing and dermatitis are not uncommon and generally disappear as the patient becomes adapted to the drug.

Hypokalemia and total-body depletion of potassium may occur in patients with urinary intestinal diversion. This is more common in patients with ureterosigmoidostomies than it is in patients who have other types of urinary intestinal diversion (Geist and Ansell, 1961). In one study, patients with ureterocolonic diversions had a 30% reduction in total body potassium, whereas those with ileal conduits had, as a group, no significant alteration in total body potassium; individually, however, some had as much as a 14% reduction in total body potassium (Williams et al, 1967). Patients with continent diversions have also been noted to have a decrease in total body potassium. The patients most susceptible to total body potassium depletion are those with long-standing uncorrected metabolic acidosis (Stein et al, 1998). The potassium depletion is probably caused by renal potassium wasting as a consequence of renal damage, osmotic diuresis, and gut loss through intestinal secretion. The last-mentioned (probably quantitatively) plays a relatively minor role. Indeed, it has been shown that ileal segments exposed to high concentrations of potassium in the urine reabsorb some of the potassium, whereas colon is less likely to do so (Koch et al, 1990). Thus those with ileum interposed in the urinary tract likely blunt the potassium loss by the kidney, whereas those with colon do not, which explains why patients with ureterosigmoidostomies and ureterocolonic diversions are more likely to have total body potassium depletion.

When the depletion is severe, the patient may develop a flaccid paralysis. In treating these patients, one must remember that if the hypokalemia is associated with severe hyperchloremic metabolic acidosis, treatment must involve both replacement of potassium and correction of the acidosis with bicarbonate. If the acidosis is corrected without attention to potassium replacement, severe hypokalemia may occur, marked flaccid paralysis may develop, and significant morbidity may ensue (Koff, 1975).

Because the bowel transports solutes and because its membrane is not particularly watertight, osmolality generally re-equilibrates across the bowel wall. Thus attempts to deprive a patient of water and determine osmolality as a reflection of renal function are inappropriate because the bowel alters the osmotic content. The bowel also makes the contents more alkaline, and therefore it is impossible to determine the ability of the kidney to acidify simply by measuring urinary pH in patients with urinary intestinal diversion. Finally, because urea and creatinine are reabsorbed by both the ileum and the colon, serum concentrations of urea and creatinine do not necessarily accurately reflect renal function (Koch and McDougal, 1985; McDougal and Koch, 1986).

Histologic alterations of the intestine may occur over time when urine is chronically exposed to the mucosa. Villous atrophy and the formation of pseudocrypts may occur, particularly in the ileum. These changes are patchy because there is normal ileal mucosa interspersed between these abnormalities. Submucosal inflammatory infiltrates may also be observed. There appear to be fewer changes in the colonic mucosa during the long term. In the colon, a decrease in the size of goblet cells has been described. In time, some transport processes may be altered, with some solutes less actively transported, whereas other processes of solute transport remain active (Philipson et al, 1983). The ability to establish a hyperchloremic metabolic acidosis, however, appears to be retained by most segments of ileum and colon over time. In an experimental study, chronic exposure of intestine to urine resulted in a decreased number of transporters, but those that remained were perfectly functional (Grocela and McDougal, 1999).

Altered Sensorium

Alteration of the sensorium may occur as a consequence of magnesium deficiency, drug intoxication, or abnormalities in ammonia metabolism. Patients who develop magnesium deficiency do so either secondary to nutritional depletion or in relation to magnesium wasting by the kidney in much the same way that calcium wasting occurs (see later). Alterations in the sensorium have also occurred because of diabetic hyperglycemia; however, this is not a consequence of the intestinal diversion. In such patients, reabsorption of urinary glucose can result in hyperglycemia without demonstrable glucosuria (Onwubalili, 1982). Perhaps the more common cause of an altered sensorium is altered ammonia metabolism. Ammoniogenic coma in patients with urinary intestinal diversion has been reported in those with cirrhosis (Silberman, 1958), those with altered liver function without underlying chronic liver disease (McDermott, 1957), and those with normal hepatic function as determined by serum enzyme activities (Mounger and Branson, 1972; Kaufman, 1984; Perez-Fidalgo et al, 2007). The syndrome is most commonly associated with decreased liver function, however, and even in patients in whom normal liver function has been reported, the crude methods by which it was assessed in those reports have made it impossible to confirm the absence of subtle alterations in liver function. The syndrome is most commonly found in patients with ureterosigmoidostomies but has been reported in those with ileal conduits as well (McDermott, 1957).

The treatment of ammoniogenic coma involves draining the urinary intestinal diversion, either with a rectal tube in patients with ureterosigmoidostomy or with a Foley catheter in those with a continent diversion so that the urine does not remain exposed to the intestine for extended periods. Neomycin is administered orally to reduce the ammonia load from the enteric tract, and

protein consumption is curtailed, thus limiting the nitrogen load to the patient until serum ammonium levels have returned to normal. In severe circumstances, arginine glutamate, 50 g in 1000 mL of 5% dextrose in water, may be given intravenously. This complexes the ammonia by providing substrate for the formation of glutamine (Silberman, 1958). Lactulose may be given orally or by rectum (Edwards, 1984). This complexes the ammonia in the gut and prevents its absorption. Consult the hospital pharmacist for dosages and schedules of these therapies.

Abnormal Drug Absorption

Drug intoxication has been reported in patients with urinary intestinal diversion. **Drugs more likely to be problematic are those absorbed by the gastrointestinal tract and excreted unchanged by the kidney.** Thus the excreted drug is re-exposed to the intestinal segment, which then reabsorbs it, and toxic serum levels develop. This has been reported with phenytoin (Dilantin) (Savarirayan and Dixey, 1969) and with certain antibiotics that are excreted unchanged. Although chemotherapy is usually well tolerated by patients with conduits, methotrexate toxicity has been documented in a patient with an ileal conduit (Bowyer and Davies, 1986).

A more recent study suggests that in patients with normal renal function, both those with and those without continent diversions tolerate chemotherapy well. The authors studied 23 patients with continent diversions and 19 with ileal conduits who received cisplatin, methotrexate, and vinblastine. The authors concluded that there was no difference in toxicity in patients without diversions, those with ileal conduits, and those with continent diversions. Indeed, the patients with continent diversions did not have a Foley catheter placed during the chemotherapy infusion. However, if one looks carefully at the data, it is clear that there is in fact an increased toxicity in the continent diversion group, although it did not achieve statistical significance (Srinivas et al, 1998). In patients receiving antimetabolites, it is prudent to carefully monitor the patient for toxic products that are excreted in the urine and capable of intestinal absorption, lest lethal toxic serum levels develop. **Moreover, in patients with continent diversions who are receiving chemotherapy, consideration should be given to draining the pouch while the toxic drugs are being administered.**

Osteomalacia

Osteomalacia or renal rickets occurs when mineralized bone is reduced and the osteoid component becomes excessive. Osteomalacia has been reported in patients with colocolostomy (Hassain, 1970), ileal ureters (Salahudeen et al, 1984), colon and ileal conduits, and, most commonly, ureterosigmoidostomies (Harrison, 1958; Specht, 1967). **The cause of osteomalacia may be multifactorial but commonly involves acidosis.** With persistent acidosis, the excess protons are buffered by the bone with release of bone calcium. With its release, it is excreted by the kidney. Support for the theory that chronic acidosis is causative in osteomalacia comes from those patients in whom correction of the acidosis results in remineralization of the bone (Richards et al, 1972; Siklos et al, 1980). It has also been shown, however, that major alterations in serum bicarbonate are not necessary for the development of the syndrome (Koch and McDougal, 1988; McDougal et al, 1988). Moreover, some patients with osteomalacia secondary to urinary intestinal diversion do not have bone demineralization corrected with restoration of normal acid-base balance. **These patients have been found to manifest vitamin D resistance that is independent of the acidosis.** It is likely that this resistance is of renal origin. Resistance can be overcome by supplying 1 α -hydroxycholecalciferol, a vitamin D metabolite that is much more potent than vitamin D₂. When this substrate is provided in excess amount, remineralization of bone occurs (Perry et al, 1977). Also, it has been shown that reabsorption of urinary solutes may play a role in increasing calcium excretion by the kidney. Sulfate filtered by the kidney inhibits calcium reabsorption and results in both calcium and magnesium loss by the kidney. Thus if the gut increases its sulfate reabsorption

and requires the kidney to increase sulfate excretion, this results in hypercalciuria and hypermagnesuria (McDougal and Koch, 1989). Finally, there is some evidence to indicate that the calcium-to-parathormone ratio is altered, suggesting that a resistance to parathormones develops during the long term (Tanrikut and McDougal, 2004). **Osteomalacia in urinary intestinal diversion may be caused by persistent acidosis, vitamin D resistance, and excessive calcium loss by the kidney.** It appears that the degree to which each of these contributes to the syndrome may vary from patient to patient.

It is clear that a number of metabolic problems have been obviated when meticulous attention is paid to correction of the abnormalities prospectively. If a base deficit of more than 2.5 mEq/L is corrected, some investigators have found no evidence of bone mineral density abnormalities (Stein et al, 1998). Indeed, the type of diversion does not seem to make a difference when the acidosis is taken into account and corrected (Kawakita et al, 1996). Others suggest that there is no difference in continent diversions and ileal conduits (Campanello et al, 1996); however, in such selected series, the distribution of acidosis across both groups is typically identical. It is clear that if the groups are large enough and not preselected, there is an increased incidence of acidosis in continent diversion patients. Indeed, if patients are followed long enough, some will develop bone mineral density abnormalities, particularly those who are acidotic over the long term (Incel et al, 2006). The take-home message is that if one pays meticulous attention to correction of the acidosis, bone mineral density abnormalities will probably not become a problem.

In general, patients who develop osteomalacia report lethargy; joint pain, especially in the weight-bearing joints; and proximal myopathy. Analysis of serum chemistries reveals that the calcium concentration is either low or normal. The alkaline phosphatase level is elevated, and the phosphate level is low or normal (Harrison, 1958). The treatment as indicated earlier involves correction of the acidosis and dietary supplementation of calcium. If this does not result in remineralization of the bone, the active form of vitamin D may be administered. If this is not successful, the more active metabolite of vitamin D₃, 1 α -hydroxycholecalciferol, should be administered.

Growth and Development

Considerable evidence suggests that urinary intestinal diversion has a detrimental effect on growth and development. In a study of 93 myelodysplasia patients observed for 17 to 23 years, significant aberrations in growth were noted when morphometric parameters were analyzed. Anthropometric measurements in those with urinary intestinal diversion showed a decrease in linear growth in all indices measured, with a statistically significant decrease in biacromial span and elbow-hand length (Koch et al, 1992).

Patients with long-term urinary diversions are more susceptible to fractures and to complications after orthopedic procedures. When myelodysplastic patients with ileal conduits were compared with a similar group of patients who retained their bladder and were on intermittent catheterization, the patients with an ileal conduit had an increased number of fractures, as well as malunions and nonunions after orthopedic procedures (Koch et al, 1992). It was found that more patients with urinary intestinal diversion fell below the tenth percentile than did patients who were treated with intermittent catheterization. There was, in fact, no difference in height and weight between the two groups studied (Koch et al, 1992; McDougal, 1992).

There is also experimental evidence for impaired linear growth in urinary intestinal diversion. Rats with unilateral ureterosigmoidostomies observed long term demonstrated significantly decreased femoral bone length compared with nondiverted controls (Koch and McDougal, 1988). Thus it appears clear that although obvious alterations in growth and development do not occur, when carefully studied, patients who have urinary intestinal diversions constructed in childhood and who maintain these diversions for more than 10 years have significant changes in linear growth.

Infection

An increased incidence of bacteriuria, bacteremia, and septic episodes occurs in patients with bowel interposition. A significant number of patients with intestinal cystoplasty develop pyelonephritis, and 13% have septic and major infectious complications (Kuss et al, 1970). The episodes are more frequent after colocolostomy than ileocolostomy (Kuss et al, 1970). In a contemporary series, 4% of patients were admitted to a hospital for sepsis (Studer et al, 2006). Acute pyelonephritis occurs in 10% to 17% of patients with colon and ileal conduits (Schmidt et al, 1973; Schwarz and Jeffs, 1975; Hagen-Cook and Althausen, 1979). Approximately 4% of patients (8 of 178) with ileal conduits die of sepsis (Schmidt et al, 1973).

Patients with conduits have a high incidence of bacteriuria. Indeed, approximately three quarters of ileal conduit urine specimens are infected (Guinan et al, 1972; Middleton and Hendren, 1976; Elder et al, 1979). It is clear that some patients are merely colonized at the distal end of the conduit because the incidence of positive cultures can be markedly diminished by culture of the proximal portion of the loop by a double-catheter technique (Smith, 1972). Many of these patients, however, show no untoward effects and seem to do well with chronic bacteriuria. Deterioration of the upper tracts is more likely when the culture becomes dominant for *Proteus* or *Pseudomonas*. Thus patients with relatively pure cultures of *Proteus* or *Pseudomonas* should be treated, whereas those with mixed cultures may, in general, be observed, provided they are not symptomatic. Patients with continent diversions also have a significant incidence of bacteriuria and septic episodes (McDougal, 1986). Indeed, two thirds of patients with Kock continent diversions have positive cultures (Kock, 1987). The reasons for the increased incidence of bacteriuria and sepsis are unclear, but it is likely that the intestine is incapable of inhibiting bacterial proliferation, in contrast to the urothelium. Thus intestine that normally lives symbiotically with bacteria when interposed in the urinary tract serves as a source for ascending infection and septic complications. Moreover, the intestine may make the urine less bacteriostatic and thereby promote the growth of bacteria. Distention of the intestinal segment may aid in translocation of bacteria across the intestine and into the blood. Studies have shown some changes in intestinal mucosal immunologic bacterial defense mechanisms; however, for the most part they seem to be preserved (Wullt et al, 2004).

Stones

One of the consequences of persistent infection is the development of magnesium ammonium phosphate stones. Indeed, the great majority of stones formed in patients with urinary intestinal diversions are composed of calcium, magnesium, and ammonium phosphate. Those most susceptible to development of renal calculi are patients who have hyperchloremic metabolic acidosis, preexisting pyelonephritis, and urinary tract infection with a urea-splitting organism (Dretler, 1973). The incidence of renal stones is 3% to 4% in patients with colon conduits (Althausen et al, 1978; Hagen-Cook and Althausen, 1979) and 10% to 12% in those with ileal conduits (Schmidt et al, 1973). In those with continent cecal reservoirs, there is a 20% incidence of calculi within the reservoir (Ashken, 1987). The stones may be a result of persistent infection with alkalization of the urine, persistent hypercalciuria for reasons described previously, and alterations of urinary excretion products by the intestine. A major cause of calculus formation in conduits and pouches is a foreign body such as a staple or nonabsorbable suture, on which concretions form. In intestinal reservoirs, alterations in bowel mucosa may also serve as a nidus for stone formation. Finally, alterations in intestinal mucus, particularly in the presence of infection or obstruction, may serve as a nidus or, more important, may interfere with emptying and thereby exacerbate infection and stone formation (N'Dow et al, 2004).

Intestinal Motility, Short Bowel, and Nutritional Problems

Many nutritional problems may occur from the loss of significant intestinal absorptive surface resulting from removal of substantial portions of the gut for construction of a urinary intestinal diversion. In patients with a significant loss of ileum, vitamin B₁₂ malabsorption has been reported and results in anemia and neurologic abnormalities. Vitamin B₁₂ deficiency has been shown to occur in 10 of 41 patients who received preoperative radiotherapy before radical cystectomy and ileal ureterostomy (Kinn and Lantz, 1984), and 21% of children who have undergone ileocolostomy have low serum levels of vitamin B₁₂ (Rosenbaum et al, 2008). Loss of significant portions of ileum also results in malabsorption of bile salts. Because the ileum is the major site of bile salt reabsorption, the lack of reabsorption allows bile salts entry into the colon, which causes mucosal irritation and diarrhea. Also, loss of the ileum results in the loss of the "ileal break." The ileal break is a mechanism whereby gut motility is reduced when lipids come in contact with the ileal mucosa so that increased absorption can occur. With the loss of ileum, the lipid does not result in decreased motility and is presented unmetabolized to the colon, which may cause fatty diarrhea.

It has been difficult to demonstrate untoward effects of low serum vitamin B₁₂ levels in these patients. The liver stores enough vitamin B₁₂ to supply the body's requirement for 3 to 5 years without oral intake. Thus pathologic problems would not be expected to manifest themselves for many years and have rarely been reported. Moreover, low serum levels of vitamin B₁₂ do not necessarily correlate with metabolic deficiency. To assess whether or not there is a metabolic impact, it is necessary to measure serum levels of homocysteine and/or methylmalonic acid. Because vitamin B₁₂ serves as a coenzyme in the metabolic pathways of homocysteine and methylmalonic acid, their measurement is a sensitive indicator of whether the low vitamin B₁₂ level is significant. These measurements have not been done in this group of patients, and thus it is unclear at this time as to the importance of vitamin B₁₂ measurements in these patients. Many physicians, however, empirically give parenteral vitamin B₁₂ as a precaution to patients who have had intestinal diversions of ileum in place for more than 5 to 7 years.

Loss of the ileocecal valve may have a number of untoward effects. Because of the loss of the valve, reflux of large concentrations of bacteria into the ileum may occur, resulting in small intestinal bacterial overgrowth. This may result in nutritional abnormalities that involve interference with fatty acid reabsorption and bile salt interaction. With the lack of absorption of fats and bile salts, these are presented to the colon and result in diarrhea. Moreover, reflux of bacteria into the small bowel may result in bile salt deficiency. Also, the lack of fat absorption may result in deficiencies of the fat-soluble vitamin A, osteomalacia caused by lack of vitamin D, and complexing of calcium with the fats to form soaps, thus preventing its absorption. The ileocecal valve also serves as a break, and an intact valve prolongs transit time of the small bowel and enhances absorption. Thus its loss may contribute to nutritional abnormalities. Some have advocated reconstruction of the valve mechanism between ileum and colon when the ileocecal segment is used for reconstruction.

Loss of a significant portion of jejunum may result in malabsorption of fat, calcium, and folic acid; however, significant portions of jejunum are rarely used for urologic reconstructive procedures. Loss of the colon may result in diarrhea because of lack of fluid and electrolyte absorption, loss of bicarbonate because of its increased secretion in the ileum and lack of reabsorption, and dehydration because of the loss of fluids.

Of concern when intestinal segments are used in urinary reconstruction is the effect removal of a segment of intestine from the alimentary tract might have on intrinsic bowel function. Indeed, removal of major segments from the alimentary tract may cause nocturnal bowel movements, fecal urgency, fecal incontinence, diarrhea, and nutritional deficiencies (Riddick et al, 2004). A study compared patients with ileal conduits with those who had segments

used for clam cystoplasty and, not surprising, found that those with clam cystoplasty had a 40% incidence of significant bowel problems. It is known that there is an association between detrusor instability and irritable bowel, perhaps accounting for the incidence of untoward disorders of bowel function in this series (N'Dow et al, 1998). Thus there is a need for heightened awareness of bowel dysfunction in patients with detrusor instability in whom bowel segments are to be used. A recent report of patients who had an ileocystoplasty noted that 7% had significant diarrhea (Blaivas et al, 2005). One should warn patients who will have major portions of the intestinal tract used in the reconstruction that bowel problems may ensue.

Cancer

The incidence of cancer development in patients with ureterosigmoidostomy varies between 6% and 29%, with a mean of 11% (Schipper and Decter, 1981; Stewart et al, 1982; Zabbo and Kay, 1986). In general, there is a 10- to 20-year delay before the cancer manifests. **On histologic examination, the tumors include adenocarcinoma, adenomatous polyps, sarcomas, and transitional cell carcinoma.** Case reports of tumors developing in patients with ileal conduits, colon conduits, bladder augmentations, rectal bladder, neobladders, and ileal ureters have been described (Austen and Kalble, 2004). Anaplastic carcinomas and adenomatous polyps have been reported in patients with ileal conduits. Adenocarcinoma has developed in patients with colon conduits; adenocarcinoma, undifferentiated carcinoma, sarcomas, and transitional cell carcinomas have developed in patients with bladder augmentations with both ileum and colon (Filmer, 1986).

The causative mechanism of the development of the carcinoma is not understood. Whether the tumor arises from transitional epithelium or colonic epithelium is unclear. Because most of the tumors are adenocarcinomas, it has been assumed that the tumor arises from the intestinal epithelium. Adenocarcinomas have been shown to arise from transitional cell epithelium exposed to the fecal stream in experimental animals (Aaronson et al, 1989). Furthermore, studies show that the ureters in ureterosigmoidostomy patients have an exceedingly high incidence of dysplasia (Aaronson and Sinclair-Smith, 1984). Moreover, if the transitional epithelium is removed from the enteric tract, adenocarcinomas do not develop. **If the urothelium is left in contact with the intestinal mucosa, however, even though the diversion is defunctionalized and the area is not bathed in urine, adenocarcinoma may still develop.** This is illustrated by a case report in which a patient who had a ureterosigmoidostomy that was defunctionalized with a conduit subsequently developed cancer 9 months later. The distal ureters at the sigmoid were left in situ. Twenty-two years later, the patient developed cancer at the site of the ureterointestinal anastomosis (Schipper and Decter, 1981). This suggests that **when ureterointestinal anastomoses are defunctionalized, they should be excised rather than merely ligated and left in situ.** Other evidence including cell staining techniques suggests that the colon is the primary organ of origin (Mundy, personal communication, 1991). Whether the urothelium or intestine is the primary site of origin, it seems likely that tumors can arise from both tissues.

The highest incidence of cancer occurs when the transitional epithelium is juxtaposed to the colonic epithelium and both are bathed by feces (Shands et al, 1989). Nitrosamines, known mutagens, are produced in rats with ureterosigmoidostomy (Cohen et al, 1987), but there appears at least at this juncture no convincing evidence to support a primary role for them in the genesis of the tumor. An abnormal pattern of colonic mucin secretion has been demonstrated in patients with ureterosigmoidostomy, but its significance is unclear (Iannoni et al, 1986). Induction of specific enzymes associated with carcinoma has also been demonstrated. Ornithine decarboxylase, an enzyme that has been found to be elevated in malignant colonic mucosa, is also elevated in experimental animals with vesicosigmoidostomy (Weber et al, 1988). The role of epidermal growth factor and other growth factors is currently being investigated. Evidence suggests that these may at least play a

role in development, if not in induction. At this time, the cause of the genesis of cancer in urinary intestinal diversion is not known. **Because its incidence is significant in patients with ureterosigmoidostomies, they should have routine colonoscopies on a scheduled periodic basis.**

Neuromechanical Aspects of Intestinal Segments

Both small bowel and colon contract to propel luminal contents in an aboral direction. The ability to propel luminal contents is a consequence of muscle activity, as well as coordinated nerve activity. Both the small bowel and the colon have an outer longitudinal layer of muscle and an inner circular layer. There is also a muscularis mucosa, which is immediately beneath the mucosa and may extend into the villi. The outer and inner layers of muscle, however, play the major role in peristalsis. In the colon, the outer longitudinal layer of muscle condenses to form three taeniae coli. The bowel receives its parasympathetic innervation from the vagus. It is also innervated by the sympathetic nervous system. The nerves lie between the circular and longitudinal layers of muscle. The enteric nervous system operates autonomously, and therefore one can denervate the intestine and not affect the coordinated contractions. These contractions are termed *activity fronts* and may be stimulated by feeding, or they may be inhibited by exposure of the lumen to various substances (e.g., lipid in the ileum decreases ileal motility). Two aspects of neuromechanical properties are particularly germane to urinary intestinal diversion: volume-pressure relationships and motor activity.

Volume-Pressure Considerations

The volume-pressure relationships depend on the configuration of the bowel. If one splits the bowel segment and turns it back on itself, the volume may be doubled if the ends are not closed (Fig. 97-41). In reconstruction of intestinal segments for the urinary tract, however, one must close the ends. Thus the limit of doubling the volume is never quite reached. Indeed, the greater the ratio of length to diameter, the greater the volume change when the ends are closed. If the ends are closed when a ratio of diameter to length of 1:3.5 is reached, splitting the segment no longer increases the volume. By splitting most segments, one is, in fact, increasing the volume by about 50%. The goal in reconfiguring the bowel is to achieve a spheric storage vessel. This

Figure 97-41. Effect of "detubularization." The bowel is split on its antimesenteric border and divided in two. When the two segments are placed together, the circumference is doubled, thus doubling the volume. Closing the ends of the cylinder requires a reduction in its length equal to the radius of the end. This limits the increase in volume that occurs by reconfiguration.

configuration has the most volume for the least surface area. By increasing the volume, it has been suggested that pressure relationships within the confines of the intestine are reduced. This is based on Laplace's law, which states that for a sphere, the tension of its wall is proportional to the product of the radius and pressure. Thus theoretically, for a given wall tension, the greater the radius, the smaller the generated pressure. This is desirable in an attempt to prevent deterioration of the upper tracts or incontinence. This relationship (Laplace's law), however, may not be accurately reflected for intestinal segments because they are not perfectly spheric, and the intestinal wall does not conform to Hooke's law but rather demonstrates viscoelastic properties, which tend to distort the relationship between pressure applied at the wall and tension generated in it. In any event, it seems desirable to attempt to construct as spheric a container as possible if one is attempting to make a reservoir.

Over time, the volume capacity of segments increases. This occurs only if they are frequently filled. Their volume decreases with time if they are nonfunctional (Kock et al, 1978). Over time, it can be demonstrated that there is a marked accommodation in volume of pouches made from intestine. For ileal pouches, it has been shown that the capacity increases sevenfold after 1 year (Berglund et al, 1987). As the reservoirs increase in volume, there is a significant increase in smooth muscle thickness of the bowel wall (Philipson et al, 1983).

Motor Activity

It has been suggested that splitting the bowel on its antimesenteric border discoordinates motor activity and thereby causes a lesser intraluminal pressure. Clearly, the ideal situation is to provide the patient with a spheric vessel that has few or ineffective contractions of its walls. It can be demonstrated in experimental animals that after the bowel wall has been split on its antimesenteric border and reconfigured, acutely there is a marked interruption of coordinated activity fronts, which over a period of 3 months return to their normal coordinated state (Concepcion et al, 1988). This has also been demonstrated clinically: Initially after reconfiguration of the bowel (detubularization), coordinated activity fronts have been shown to decrease. During extended periods, however, many of the peristaltic waves (activity fronts) reappear and can be readily demonstrated (Fig. 97-42).

The literature is contradictory with respect to the effect of detubularization on segments of ileum and colon used to construct storage vessels for continent diversions. Pressure within the lumen of bowel that has both ends closed may be increased by adding volume or reducing the size of the bowel through contractions of its wall. Because the bowel wall is freely permeable to water, the higher osmotic content of urine obligates movement of water into the bowel lumen. Most patients with continent diversions excrete 2 to 4 L/day (McDougal, 1986). In evaluating whether motor activity is the primary determinant of intravesical pressure, one must be cognizant of fluid volume changes. Also, as indicated previously, early reports of detubularized segments would be

expected to differ from later reports when coordinated activity fronts in these segments return.

These facts are often forgotten, and because pressure measurements are used to infer motor activity, rather than its direct measurement as reflected by changes in bowel wall tension, it is not difficult to understand why there are so many contradictions reported in the literature. Detubularization of ileal segments has been reported by some to decrease motor activity at a year compared with immediately postoperatively (Berglund et al, 1987), whereas others have noted increased motor activity at 1 year. Involuntary pressure waves occur in 25% of patients with Kock pouches. Maximum intravesical pressures average 41 cm H₂O in these pouches (Chen et al, 1989). Ileum has also been shown to have fewer activity fronts per unit of time than cecum (Berglund et al, 1986). Cecum has been observed to have the same number of activity fronts 1 year postoperatively, but the amplitude of the pressure waves has been observed to decrease over time (Hedlund et al, 1984). Maximum pressures in normal cecum have been shown to range from 18 to 100 cm H₂O (Jakobsen et al, 1987), whereas detubularized cecum has been shown to have pressures that range from 5 to 25 cm H₂O 1 year postoperatively (Hedlund et al, 1984). Others, comparing ileum to cecum, find no difference in pressure generated after a year (Hedlund et al, 1984). The Mainz pouch, which uses both ileum and cecum, has an average pressure at capacity of 39 cm H₂O with a maximum pressure of 63 cm H₂O (Thuroff

Figure 97-42. Pressure waves recorded 1 year postoperatively in a patient with a continent diversion constructed from detubularized ileum and right colon. Notice that the coordinated pressure waves are of magnitude and frequency similar to those found in a normal colonic or ileal segment.

KEY POINTS

- Although 15 cm of small bowel can survive beyond the last vessel, it is unwise to assume that more than 8 cm of small bowel will survive beyond a straight vessel.
- The bacterial concentration ranges from 10^4 to 10^5 in the jejunum, 10^5 to 10^7 in the distal ileum, 10^6 to 10^8 in the ascending colon, and 10^{10} to 10^{12} in the descending colon.
- A mechanical bowel preparation reduces the total number of bacteria, not their concentration.
- The guiding principles of a proper intestinal anastomosis include adequate exposure, good blood supply, prevention of spillage of enteric contents, accurate apposition of the serosa of the two segments of bowel, proper tension of the sutures, and realignment of the mesentery of the two segments.
- After a ureteral anastomosis, deterioration of the upper tracts in the long term is usually caused by a lack of ureteral motility, infection, or stones and less commonly by a stricture at the anastomotic site.
- Antirefluxing ureteral-intestinal anastomoses have a higher rate of stricture than refluxing anastomoses.
- Limited segments of bowel should be used in patients who have an inability to acidify the urine to less than 5.8, an inability to concentrate greater than 600 mOsm/kg, or a GFR less than 35 mL/min.
- Metabolic complications of intestine interposed in the urinary tract include electrolyte abnormalities, altered sensorium, abnormal drug metabolism, osteomalacia, growth retardation, persistent and recurrent urinary tract infection, formation of calculi, short gut, and development of urothelial or intestinal cancers.
- Those gastrectomy patients most at risk for the development of the syndrome of severe metabolic alkalosis are those with high resting levels of serum gastrin who overdistend their pouches and are dehydrated.
- The electrolyte abnormality that occurs with ileum and colon is a hyperchloremic metabolic acidosis.
- Patients receiving chemotherapy who have intestine interposed in the urinary tract have increased toxic effects of chemotherapeutic agents compared with patients with normal urinary tracts.

et al, 1987). Thus, reconfiguring bowel usually increases the volume, but its long-term effect on motor activity and wall tension is unclear at this time. It has been my observation that some patients with orthotopic bladders after a number of years of spontaneous voiding require intermittent catheterization. In these patients the bowel segment has become flaccid, and the ability of the patient to generate intraluminal pressure by a Valsalva maneuver is limited.

SUMMARY

This chapter has addressed complications both independent of and dependent on the specific type of urinary intestinal diversion. Each unique type of diversion has its own set of individual complications. Moreover, the procedure preceding the urinary intestinal diversion also has a set of complications that must be added to those described previously. It is clear that with current modalities of urinary intestinal diversion, long-term complications significantly contribute to mortality and morbidity. Many patients who have intestinal diversion after an extirpative procedure for cancer, however, die of the cancer rather than of these long-term complications. Those for whom a urinary intestinal diversion has been constructed for benign disease and those who are cured of cancer are most likely to experience long-term morbid complications. The knowledge of the frequency of these complications and the correct performance of preoperative preparation, surgical technique, and postoperative care, as outlined in this chapter, should provide the best chance for the least mortality and morbidity in patients undergoing urinary intestinal diversion.

General Considerations

Continent Urinary Diversion

Quality-of-Life Assessments

Variations in Operative Technique

Summary

GENERAL CONSIDERATIONS

Continent urinary diversion is widely accepted by both urologist and patient alike as an acceptable form of urinary reconstruction after cystectomy. Orthotopic urethral anastomotic procedures and continent catheterizable stomal reservoirs have stood the test of time, and both procedures should be considered for all appropriate patients. Orthotopic continent diversion and the metabolic consequences of continent urinary diversion are covered in separate chapters and are not discussed in detail here. This chapter focuses on the most common continent cutaneous diversion surgeries associated with the highest success rates. Over the past 35 years the design of the reservoir has not substantially changed. However, an evolution has occurred in the techniques used to create anti-reflux and continence mechanisms to make them more effective and reliable. In addition, attention will be given to the long-term quality-of-life outcomes of continent cutaneous reservoirs, as well as to the newer laparoscopic and robotic approaches used to create such reservoirs.

Despite the considerable enthusiasm for continent urinary diversion operations, those procedures requiring the use of external urinary collecting appliances remain more common. Although continent urinary diversion is certainly appropriate in selected patients, the procedures are technically more challenging and are associated with higher short-term and long-term complication rates than those that use external collecting devices. However, the operating time associated with these more complex procedures has been significantly reduced by the widespread use of absorbable and metal staples in the construction of the reservoirs and limbs. These techniques are discussed in detail later. Also, as experience with continent urinary diversion has grown, complication rates have decreased. As a result, the use of continent diversions has increased in some centers.

Patient Selection

Because the ability to self-catheterize is essential to the patient undergoing continent diversion, the patient must be assessed for the ability to care for himself or herself. Consultation between an enterostomal therapist and the patient is extremely helpful in this regard, because the patient may be at greater ease with the therapist and more willing to express any concerns. Certain patients may not be able to comprehend the strict flushing and catheterization regimens that must be followed after continent urinary diversion or may lack the motor skills to independently perform self-care. **Patients with multiple sclerosis, quadriplegic individuals, and very frail or mentally impaired patients will at some point in their lives require family or visiting nurses for basic care and are therefore viewed as poor candidates for any form of continent diversion.** Indeed, these patients may also require assistance with external appliances, but the degree of time and expertise required

is much less burdensome on the care provider and the health care system. On the contrary, continent catheterizable diversion requires continuous attention and may limit patient and family options when determining long-term care needs.

Patient Preparation

All patients undergoing anticipated continent urinary diversion should be prepared for the possibility that a traditional ileal conduit procedure might be performed. Although it is rare to abandon a continent diversion owing to intraoperative findings, this always remains a possibility. Therefore before the operation is started, the site for an external stoma should be selected with care. In general, the location must be free from fat creases in both the standing and sitting positions and it should not be close to prior abdominal scars that may interfere with proper adherence of an external appliance. Here again, the aid of an enterostomal therapist is helpful. In general, the stoma should be brought through the right (or left) lower quadrant of the abdomen on a line extending from the umbilicus to the anterior superior iliac spine. The stoma should be as far lateral from the midline as possible, but the site selected should ensure that the bowel segment comprising the stoma traverses the rectus muscle. Failure to adhere to this rule increases the risk of parastomal hernias. The selected site for the stoma should be marked with an X scratched onto the anterior abdominal wall. Marking the stoma site with ink should be avoided because it may be washed away during the antiseptic preparation of the skin.

The surgeon undertaking continent urinary diversion should be familiar with more than one type of continent diversion technique. Although it is uncommon to have to abandon a given bowel segment for the reservoir, it is not uncommon to have to modify the antireflux or continence mechanism. In these circumstances, it is essential that the surgeon be able to select an alternate form of continent diversion from what was originally intended.

Renal and hepatic function must be reviewed carefully in the patient selected for continent diversion (Mills and Studer, 1999). The reabsorption and recirculation of urinary constituents and other metabolites require that liver function be normal. Renal function should be determined preoperatively, and if borderline, creatinine clearance should be measured. A minimal level of 60 mL/min should be documented before the patient is deemed an appropriate candidate for continent diversion. In patients with bilateral hydro-nephrosis in whom renal functional improvement might be anticipated on relief of the ureteral obstruction, the upper urinary tract should first be decompressed with either ureteral stenting or percutaneous nephrostomy (or nephrostomies), with subsequent reevaluation of renal function before consideration for a continent diversion.

Procedures that will require the use of the colon should always be preceded by a colonoscopic assessment of the entire large intestine. Performing only a sigmoidoscopy for a procedure that will use

only this segment of the large bowel is insufficient because disease proximal to the resected segment may leave the patient with short colon syndrome. The preoperative assessment of the colon is not necessary if continent urinary diversion using small intestine is planned.

Healthy patients undergoing radical cystectomy can be admitted to the hospital on the day of surgery. In most institutions a mechanical bowel preparation is employed on the day before surgery, in addition to oral metronidazole (500 mg) the night before. However, in addition to general surgery literature, several nonrandomized urologic studies have called into question the usefulness of the preoperative bowel preparation (Large et al, 2012; Raynor et al, 2013). Intraoperative antibiotics (e.g., cefoxitin 1 to 2 g) should be administered within 1 hour of skin incision.

Cystectomy

All operations described require a midline incision, skirting the umbilicus to the side opposite the selected stoma site. The incision for a right colon pouch usually extends from the pubis to a point midway between the umbilicus and the xiphoid. The cranial extent of the incision is governed by the hepatic flexure, which must be divided to obtain sufficient colonic length and to allow for the right colon to easily fold on itself. On some occasions the incision will be extended to the xiphoid. The incision for procedures using only the ileum should extend to just below the umbilicus. The cystectomy procedure is covered elsewhere in this text, and only those points germane to continent diversion are covered here.

After abdominal exploration, the ureters are isolated, transected, and transposed to an appropriate place for subsequent diversion. The right retroperitoneum is first opened over the iliac artery to expose the right ureter. In the typical circumstance of conduit diversion, the right ureter is transected below the common iliac artery. For all continent diversions, both ureters are transected as low as possible and shortened to the appropriate length once the final anatomy has been determined. The sigmoid colon is freed from its lateral peritoneal attachments by incising along the line of Toldt. A wide tunnel is created by blunt finger dissection ventral to the aorta and common iliac arteries and caudal to the inferior mesenteric artery. This affords left ureteral access to the previously exposed right retroperitoneum. In cases of uroepithelial malignancy, it is prudent to evaluate the margin status of the most distal portion of both ureters using frozen-section analysis. In situations in which substantial ureteral length is removed to obtain negative surgical margins, extension of the afferent limb mechanism may be necessary to allow tension-free ureteral intestinal anastomoses.

All sutures used in the urinary tract should be absorbable. The individual surgeon's preference will dictate the caliber and type of suture material used. In carrying out bowel surgery for continent urinary diversions, stapling is the preferred method for division of the bowel segment as well as for reconstruction of bowel continuity. This technique shortens operative times greatly and affords safe and reliable bowel anastomosis. Suturing is not necessary with the exception of placing two silk Lembert sutures at the apex of side-to-side stapled bowel anastomoses to prevent tension on the staple line. To avoid stone formation on the stapled proximal bowel segments, oversewing the stapled end of the conduit with absorbable material isolates the metal staple line from urinary contact within the lumen.

In constructing a nonappendiceal continent urinary diversion stoma, a skin button matching the diameter of the structure to be used in the diversion is resected. Cutaneous tissues are separated down to the level of the anterior rectus fascia, where a circle of similar diameter is excised from this fascia, or alternatively the fascia is incised in a cruciate fashion. In carrying out this maneuver, it is essential that the fascia and skin are properly aligned to avoid angulation. Rectus muscle fibers are separated bluntly and an instrument is passed through the posterior fascia and peritoneum. For appendiceal stomas, we prefer to perform a Y-shaped cutaneous incision that allows for a YV-type plasty

incision between the appendiceal limb and the skin (Fig. 98-1). This will decrease the likelihood of subsequent stomal stenosis. Alternatively, the appendix lends itself to an umbilical stoma (Bissada, 1993; Gerharz et al, 1997). Favorable results with this appendiceal YV plasty technique to the umbilical site have been reported (Bissada, 1998).

It is standard procedure to use long, end-hole single J-type diverting stents in all continent cutaneous urinary diversions. These stents drain urine externally, ensuring that urine is safely diverted beyond any anastomotic site during the early healing period. They can also be safely manipulated or exchanged if necessary. The end hole allows for the passage of a straight wire through the stent, which decreases the likelihood of anastomotic trauma at the time of stent removal.

We advocate the use of closed suction drains in all cases of urinary diversion. Soft silicone Jackson-Pratt closed suction drains are preferred because they have less potential for tissue damage or migration into pouches.

Abdominal closure is performed according to the surgeon's preference. A single-layer closure with No. 2 nylon, Surgilene, or Prolene taken through all layers of fascia and muscle usually provides a rapid and secure abdominal closure in the majority of patients. In obese patients, those with tissues of poor quality, or nutritionally depleted patients, through-and-through stay sutures are also used. Ureteral stents are always brought through separate abdominal stab wounds, sutured to the anterior abdominal wall, and directed into separate drainage bags for monitoring of urine output. Even at this early stage it is important to ensure adequate drainage of the reservoir to prevent pouch rupture should the ureteral stents be displaced. In the case of limited pouch access such as with an appendiceal stoma, a Malecot tube should be placed directly into the reservoir and secured to the skin. The reservoir is sutured to the abdominal wall to prevent urine leakage into the peritoneal cavity when the tube is removed. This maneuver also helps to prevent migration and angulation of the reservoir, which could result in incontinence or catheterization difficulties.

Postoperative Care and Comments

Paralytic ileus is a common complication after urinary diversion procedures. Gastric decompression should be maintained until extubation. This can be achieved in the majority of patients by means of nasogastric intubation. However, certain patients may best be managed by formal gastrostomy decompression inserted intraoperatively. These individuals include those with multiple prior abdominal procedures in whom prolonged ileus is more likely. If the patient is nutritionally depleted preoperatively, hyperalimentation has been suggested to be of value if initiated during the preoperative interval (Hensle, 1983; Askanazi et al, 1985). However, in a recent randomized controlled trial, postoperative total parenteral nutrition was found to increase infectious complications in nutritionally noncompromised patients (Roth et al, 2013).

Ureteral stents are usually removed 1 week after surgery. Before any manipulation, a urine sample from each stent should be sent for culture and sensitivity testing. Before stent removal, radiographs of the pouch may be obtained to ensure that the pouch is intact. Radiologic contrast studies are performed to ensure against ureteral anastomotic leakage. Each stent is injected with contrast agent in a search for extravasation; if none is seen, guidewires are advanced to each kidney and the stents are removed. If there is any question of extravasation, stents can be advanced over the wires, positioned fluoroscopically, and left in situ for reevaluation after additional healing time.

Late malignancy has been reported in all bowel segments exposed to the urinary stream, whether or not there is a commingling with feces (Filmer and Spencer, 1990; Shokeir et al, 1995). A study by Gitlin and colleagues (1999) suggests that the malignancy may develop from the urothelial component and not as a result of urine affecting intestinal mucosa. As a result, urinary cytology should be performed for all patients undergoing a

Figure 98-1. A to C, A V-flap is incised in the skin, and a similar-length incision is made on the adjacent appendiceal surface. This is similar to the technique used to mature a cutaneous ureterostomy. For an appendiceal stoma, no eversion is required. (From Hinman F Jr: *Atlas of urologic surgery*. Philadelphia: Saunders; 1989.)

continent urinary diversion, whether or not the diversion was performed secondary to a urothelial malignancy. When the ureters are directed into the fecal stream, routine colonoscopy should also be performed. Latency periods as short as 5 years have been reported; therefore all patients developing gross or microscopic hematuria should be fully evaluated (Golomb et al, 1989). If an anastomotic transitional cell cancer is discovered, the patient should be fully evaluated with upper tract imaging and ureteroscopy if possible. Antegrade ureteropyeloscopy can be employed if necessary. For an isolated anastomotic recurrence, distal ureterectomy and reimplantation may be appropriate. If nephroureterectomy is necessary, some patients may require removal of their continent diversion because of resulting renal insufficiency.

CONTINENT URINARY DIVERSION

Continent, nonorthotopic urinary diversion can be divided into two major categories. First, the variations of ureterosigmoidostomy such as ileocecal sigmoidostomy, rectal bladder, and the sigmoid hemi-Kock operation with proximal colonic intussusception allow for excretion of urine by means of evacuation. Second is the large category of continent diversions requiring clean intermittent catheterization of the constructed pouch for urine drainage at standard intervals.

The concept of refashioning bowel so that it serves as a urinary reservoir rather than a conduit has become universally accepted. This concept is based on original pioneering observations by Goodwin and others in the development of the cystoplasty augmentation procedure (Goodwin et al, 1958). The destruction of peristaltic integrity and refashioning of bowel has led to the development of many innovative urinary reservoirs constructed from bowel. Several procedures have been developed to prevent or reduce

damage to the upper urinary tract from sepsis or increased pressure from ureteral reflux, and other techniques have evolved to achieve and maintain urinary continence.

Because numerous variants of continent urinary diversion are used worldwide, a complete review of all operative techniques is beyond the scope of this or any chapter. However, many of these procedures are simple modifications of parent operations. In this chapter we describe in detail each parent operation as well as major modifications. The very fact that there are many continent urinary diversion procedures reveals an obvious corresponding fact: the “best” continent diversion has yet to be devised. There is, to date, no consensus that would indicate that one continent cutaneous diversion is superior to another, but it is becoming apparent that certain procedures are associated with lower early and late complication rates. Points of controversy include (1) which bowel segment is most appropriate for fashioning into a urinary reservoir, (2) the best techniques for achieving urinary continence, and (3) the best method for preventing urinary reflux into the upper tracts. There are now various continence mechanisms that appear reliable. In our experience, procedures using a right colon reservoir with some form of appendiceal continence mechanism are the fastest and easiest to perform.

It should be reemphasized that all continent diversions will allow for substantial reabsorption of urinary constituents that will place an increased workload on the kidneys (Mills and Studer, 1999). No patient with substantial renal impairment should be considered for any of these procedures. The long-term sequelae of continent urinary diversion are well understood and, unfortunately, commonly involve significant renal damage. Although it has been suggested that the absence of reflux into the upper urinary tracts in catheterizable pouches may reduce the long-term impact of continent diversion procedures on renal function, it should be cautioned that long-term 15-year data are available and that in some instances antireflux procedures are associated with a higher risk of

obstruction caused by anastomotic stricture (Kristjansson et al, 1995; Hohenfellner et al, 2002). In addition to increased stricture rates, it is not clear whether antirefluxing mechanisms actually result in improved preservation of the upper tracts (Pantuck et al, 2000).

The process of patient counseling that we employ always refers to ileal conduit diversion as the gold standard against which the newer, more complex operations must be compared. The patient should be advised that continent diversion is, all other considerations being equal, associated with a longer hospital stay, as well as higher complication rates and greater potential for requiring reoperative surgery. Nieuwenhuijzen and colleagues (2008) reported on 281 consecutive radical cystectomies with urinary diversion using ileal conduit, orthotopic neobladder, or Indiana pouch. There were no significant differences in early complications among the three techniques. The incidence of late complications, including metabolic disturbances and ureteroileal anastomotic strictures, were similar between the two continent diversions but more frequent compared with patients with an ileal conduit. An extensive review from our institution has demonstrated no statistically significant difference in reoperations, mortality, or hospital stay in patients undergoing continent diversion versus conduit diversion by the same three surgeons over a 3-year period (Benson et al, 1992). Analysis of the two patient groups, on the other hand, showed that those selected for continent diversion were significantly younger and four times less likely to have significant concurrent illness. What this review suggests is that, with proper patient selection, continent diversion operations can be safely conducted with results similar to those for conduit diversion. To determine if continent diversion could be safely performed in selected elderly patients, Navon and colleagues (1995) compared the clinical course of 25 patients over the age of 75 years undergoing a modified Indiana reservoir with results in a cohort of 25 randomly selected patients younger than 75. The mean age of the first group was 78.5 years, and the mean age of the second was 59.3 years. The complication rates between the two groups were acceptably low and surprisingly similar. Navon and colleagues concluded that age alone should not be a contraindication to continent diversion and that the Indiana reservoir procedure can be successfully performed in elderly patients.

Rectal Bladder Urinary Diversion

Various innovative surgical techniques have been advocated for separating the fecal and urinary streams while still employing the principles of ureterosigmoidostomy. In general, these operations can be discussed together as rectal bladder urinary diversions. In each of these operations the ureters are transplanted into the rectal stump. The proximal sigmoid colon is managed by terminal sigmoid colostomy or, more commonly, by bringing the sigmoid to the perineum, thereby using the anal sphincter to achieve both bowel and urinary control. Although these operations continue to be commonly performed, they have never been well accepted in the United States. The principal reason is the potential for the calamitous complication of combined urinary and fecal incontinence, presumably occurring as a consequence of damage to the anal sphincter mechanism during the dissection processes (Culp, 1984).

If the urologist selects one of these procedures, the preoperative evaluation should include all of the caveats of ureterosigmoidostomy. Dilated ureters are not acceptable. Patients with extensive pelvic irradiation are not candidates, and neither are those with existing renal insufficiency. Anal sphincteric tone must be judged competent before these operations are selected. Our preference has been to use a 400- to 500-mL thin mixture of oatmeal and water that the patient is asked to retain for 1 hour in the upright position (Spimak and Caldamone, 1986). Finally, colonoscopy must be carried out before the procedure to rule out preexisting colorectal disease, and surveillance must be ensured to guard against subsequent development of colon cancer. Procedures that separate the fecal and urinary streams but drain both through the rectal sphincter are not described

here. Those seeking detailed descriptions of these procedures can find them in prior editions of this chapter. The following is a brief description of more modern surgical procedures that use the intact anal sphincter for urinary and fecal continence. However, the surgical techniques for these procedures are likewise not discussed in this edition.

Folded Rectosigmoid Bladder

A modification of the ureterointestinal anastomosis was described by a group from Mansoura, Egypt (Hafez et al, 1995; El-Mekresh et al, 1997). This procedure creates a folded rectosigmoid bladder with anastomosis of the ureters via serosa-lined tunnels rather than into the taenia coli. This procedure has the advantage of a larger sigmoid reservoir, as well as the prevention of reflux by creating the aforementioned serous-lined tunnel for the anastomosis. This reimplantation technique was first described by Abol-Enein and Ghoneim (1993) and appears to have a lower complication rate than direct taenial implantation (Hafez et al, 1995).

Postoperative Care and Comments. Patients undergoing this procedure must be closely monitored for the development of hyperchloremic acidosis. This will occur in the majority of patients, and it is wise to initiate a bicarbonate replacement program after the operation. Because hypokalemia is also a feature of ureterosigmoidostomy, replacement of potassium along with bicarbonate may be achieved with oral potassium citrate. Routine nightly insertion of a rectal tube is advocated in the long-term care of the patient. However, many patients will reject this practice as uncomfortable and unappealing. Nighttime urinary drainage should be mandated for any patient who cannot maintain electrolyte homeostasis with oral medication. Bissada and associates (1995) reported that 30 of 61 patients were able to stay dry during the night without awakening. The other 31 required two or more awakenings to remain dry overnight. Hyperchloremic acidosis was reported in 4 of 61 non-compliant patients.

In 1997, El-Mekresh and associates (1997) reported on 64 patients (32 women, 20 men, and 12 children) who underwent their rectosigmoid bladder procedure from 1992 to 1995. Follow-up ranged from 6 to 36 months. Functional results were assessable in 57 patients: 1 died of a postoperative pulmonary embolism and 6 died from their disease. All patients were continent during the day with two to four emptyings, and all but 4 remained dry at night with zero to two emptyings. Four children experienced enuresis that responded to 25 mg of imipramine at bedtime. It is important to note that upper urinary tract function was maintained or improved in 95% of patients. However, six renal units (5.3%) developed obstructive hydronephrosis secondary to ureterocolic anastomotic strictures. Two were remedied by antegrade dilation, one was repaired by open revision, and one nonfunctioning renal unit was removed. The fate of the remaining two units was not specified. No patient in this series developed postoperative metabolic acidosis. However, all patients were maintained on prophylactic oral alkalinization.

Obviously, all patients undergoing these procedures have exposure of the urinary tract to fecal flora. Most authors would advocate chronic administration of an antibacterial agent to all patients (Duckett and Gazak, 1983; Spimak and Caldamone, 1986). Ureteral strictures require reoperative surgery and are experienced in 26% to 35% of patients over time (Williams et al, 1969; Duckett and Gazak, 1983).

Because of the concern for development of rectal cancer anywhere from 5 to 50 years (average 21 years) after ureterosigmoidostomy (Ambrose, 1983), it is suggested that patients with long-term ureterosigmoidostomy undergo annual colonoscopy (Filmer and Spencer, 1990). Barium enemas are relatively contraindicated because reflux of this material into the kidneys (if the antireflux procedure fails) can result in dire consequences (Williams, 1984). Additional methods for colon carcinoma screening in this population are the evaluation of stool for blood and the attempted cytologic examination of the mixed urine and feces specimen (Filmer and Spencer, 1990).

Augmented Valved Rectum

Kock developed the augmented valved rectum technique to be used in locales where stoma appliances were not readily available (Kock et al, 1988). This operation is similar to standard ureterosigmoidostomy except that a proximal intussusception of the sigmoid colon confines the urine to a smaller surface area, thus minimizing the problems of electrolyte imbalance. In addition, the rectum is patched with ileum to improve the urodynamic properties of the rectum as a urinary reservoir. Preoperative evaluation is similar to that used in ureterosigmoidostomy. The large bowel must be studied for preexisting disease, and anal sphincteric integrity must be tested before surgery.

Hemi-Kock and T Pouch Procedures with Valved Rectum

In his description of the augmented valved rectum procedure, Kock described the use of a foreshortened hemi-Kock pouch to be used as a rectal patch when the ureters were too dilated to bring down between the leaves of the intussuscepted sigmoid (Kock et al, 1988). Skinner then modified this procedure by using an entire hemi-Kock segment to augment the rectum after sigmoid intussusception (Skinner et al, 1989).

After extensive experience with the Kock ileal reservoir, the group at the University of Southern California has attempted to improve on the intussuscepted Kock continence mechanism. The result has been the modification of the T pouch to serve as an ileal anal reservoir (Stein et al, 1999a). The technique consists of the construction of a hemi-Kock or T pouch employing doubly folded, marsupialized ileum and a proximal continence mechanism to prevent pouch-ureteral reflux. This pouch is then anastomosed to the rectum directly as a patch. Contact of urine with the proximal colon can be avoided by the intussusception of the sigmoid colon proximal to the anastomotic site (Fig. 98-2).

Postoperative Care and Comments. Postoperative management and complications associated with this operation are very similar

to those that might be experienced after any procedure that directs the urinary stream into the rectum. Radiologic studies of the stents are carried out on the seventh postoperative day. Before tent studies are conducted, a Gastrografin enema may be performed through the rectal tube to ensure that the region of ureterocolonic anastomosis is intact. Follow-up films are taken to ensure prompt drainage of the upper urinary tracts into the rectosigmoid region. The rectal tube may be removed at this point, but some believe that it is advisable to have it reinserted for evening drainage over the forthcoming week. The patient is instructed to empty the colon at intervals of no more than every 2 hours, particularly in the early postoperative period.

When the rectal tube is removed, as in other situations when the urinary tract is diverted to the rectum, the patient must be closely monitored for the development of hyperchloremic acidosis. Because hypokalemic metabolic acidosis often occurs after ureterosigmoidostomy, bicarbonate replacement with oral potassium citrate should begin in the immediate postoperative setting. Long-term care should include nightly insertion of a rectal tube despite the uncomfortable and unappealing nature of the process. In addition, nighttime urinary drainage is necessary in patients who cannot maintain electrolyte homeostasis with oral medication.

The hemi-T procedure with valved rectum has one theoretic advantage over the valved rectum operation itself: because transitional ureteral epithelium is not in contact with colonic epithelium, there may be a reduced risk of development of colonic malignancy. As in the augmented valved rectum, the proximal colonic intussusception used in this procedure decreases the contact between urine and colonic epithelium, thereby potentially decreasing the risk of hyperchloremic acidosis. Nevertheless, attention should be paid to electrolyte levels after removal of stents and rectal tubes.

Skinner and colleagues reported on the results of the hemi-Kock procedure in 15 patients from 1987 to 1991 (Simoneau and Skinner, 1995). Four patients had prior bladder exstrophy and were converted to an ileoanal reservoir, and 11 patients underwent the procedure as a form of primary diversion after cystectomy. At the time

Figure 98-2. A, A 30-cm segment of ileum is selected, the first 10 cm for the T implant and the distal 20 cm for the patch. The 20-cm segment is folded into a U and opened as shown. The medial borders are closed with running absorbable sutures. B, The ostium of the T is secured to the walls of the ileum with interrupted absorbable sutures. The wall of the ileum is closed over the T mechanism with a running absorbable suture. C, The ureters are anastomosed to the top of the T in the usual end-to-side fashion. The T patch is then secured to the 15-cm proctotomy with a two-layer closure. (From Stein JP, Buscarini M, DeFilippo RE, Skinner DG. Application of the T pouch as an ileo-anal reservoir. *J Urol* 1999b;162:2052-3.)

of the report 10 patients were still alive and could be evaluated. Early postoperative complications occurred in 3 patients (20%): a colcutaneous fistula in 2 patients, urine leak in 1, and deep venous thrombosis in another. Late complications included partial small bowel obstruction in 4 patients (with 2 requiring surgery), urinary retention requiring surgery in 2 patients, and metabolic acidosis in 5 patients. Two of the 11 patients undergoing primary construction never achieved continence; both were older than 68 years. The authors summarized their experience by concluding that the operation is best suited for the younger exstrophy patient and that it is essential to avoid colonic redundancy distal to the reservoir. The use of the T pouch as an ileoanal reservoir has been reported in 1 former exstrophy patient (Stein et al, 1999a), with no reported postoperative complications.

Sigma-Rectum Pouch, Mainz II

A variation of ureterosigmoidostomy was described by Fisch and Hohenfellner in 1991 and updated in 1996 (Fisch and Hohenfellner, 1991; Fisch et al, 1996). This operation, which they termed the *sigma-rectum* or the *Mainz II pouch*, creates a low-pressure rectosigmoid reservoir of increased capacity. They viewed the simplicity and reproducibility of the operation as two of its major advantages.

Postoperative Care and Comments. The rectal tube is removed on the 3rd to 5th postoperative day, and the ureteral stents are removed around the 8th day. On the 15th postoperative day the Mainz group performs an intravenous pyelogram to assess the upper tracts and the sigma-rectum pouch construction. Radiography of the pouch is performed on the 17th postoperative day.

The results of the Mainz II pouch were reported by Fisch and associates in 1996. From 1990 to 1993, 73 patients (59 adults and 14 children) underwent the Mainz II pouch procedure. Early complications were encountered in 5 of 73 patients (6.9%). These included single examples of a dislodged ureteral stent, pneumonia, pulmonary embolism, wound dehiscence, and ileus necessitating surgical intervention. There were eight (11%) late complications that required surgery: ureteral stenosis occurred in 5 patients (6.9%); 1 patient with nephrolithiasis was treated with extracorporeal shockwave lithotripsy; 1 patient with rupture of the anterior suture line required temporary colostomy; and 1 patient experienced perianal bleeding after chemotherapy that required endoscopic coagulation. Six patients had pyelonephritis (8.2%) and were treated with antibiotics. Daytime and nighttime continence rates were reported as 94.5% and 98.6%, respectively. Oral alkalinization to prevent metabolic acidosis was used in 49 of 73 patients (67.1%). Two patients who refused any oral medication developed metabolic acidosis. The Mainz group concluded that the overall complication rate was low and comparable to that of other techniques of continent urinary diversion.

Woodhouse and Christofides (1998) reported on their experience with the Mainz II pouch in 15 primary cystectomy patients and 4 patients with prior standard ureterosigmoidostomy who were incontinent. They reported excellent results: 14 of 15 (93.3%) of the primary patients achieved documented daytime and nighttime urinary control, and the remaining patient refused follow-up but reported continence. The 4 patients undergoing a salvage procedure fared less well. Only 2 patients became continent, and the remaining 2 were found to be in chronic retention. Their failed continence was believed to be secondary to inadequate pouch emptying. Similarly excellent results have been achieved by Venn and Mundy (1999). They reported full daytime and nighttime urinary continence in 14 of 14 patients and no major postoperative complications.

Bastian and coworkers (2004) have reported on the health-related quality of life in 83 patients undergoing Mainz II urinary diversion. They found that quality of life was similar to that of age-matched controls except for diarrhea symptoms, with 100% daytime continence.

There appears to be no metabolic advantage to this procedure, because the need for oral alkalinization is similar to that with standard ureterosigmoidostomy. In fact, the only difference between

this operation and standard ureterosigmoidostomy is the partial reconfiguration of the rectosigmoid junction. It does appear that the reduced intracolonic pressures that result from the partial reconfiguration increase the sigmoid capacity and result in better daytime and nighttime continence. Whether the increased capacity and lower pressure of this pouch will decrease the incidence of upper tract complications remains to be determined by longer follow-up.

Continent Catheterizing Pouches

Numerous operative techniques have been developed for continent diversion wherein urine is emptied at intervals by clean intermittent self-catheterization. Many of these operations are described in this chapter, although certain pioneering procedures that used intact bowel—such as those of Gilchrist and associates (1950), Ashken (1987), Mansson and colleagues (Mansson et al, 1984; Mansson, 1987), Benckroun (1987), and others—are not. This is not to discredit the pioneers in the field but simply to allow this chapter to focus on those pouches that incorporate modern principles that attempt to achieve a spheric configuration and disruption of peristalsis.

In continent urinary diversion, the two favorite sites for stomal location are (1) at the umbilicus and (2) in the lower quadrant of the abdomen, through the rectus bulge and below the “bikini line.” This location is often preferred because it affords both men and women the opportunity to conceal the stoma. The umbilicus is a preferred location for the individual confined to a wheelchair and has been reported to have a lower incidence of stomal stenosis, especially when an appendiceal stoma is fashioned. The umbilical location is also far easier for the paraplegic individual to catheterize without the need for chair transfer and disrobing. In individuals with a recessed umbilicus, the umbilical location of a stoma is barely perceptible from a normal umbilical dimple. In general, the stoma site is covered with a gauze pad or square bandage to avoid mucous soiling of clothing. Patients undergoing continent urinary diversion to an umbilical location should be advised to wear a medical alert bracelet that informs the examiner of the umbilical stoma.

Before the extension of orthotopic neobladder construction to women, there was some enthusiasm for the orthotopic placement of a catheterizing portal. This procedure has been carried out in certain female patients with success. The construction of a neourethra to the introitus is attractive, provided there is no substantial difficulty in the catheterizing process. Because it can be difficult to direct a catheter through the “chimney” of an intussuscepted nipple valve, those continent diversions employing nipple valves are not particularly adaptable to orthotopic location, although they have been performed with success in a small number of patients (Olsson, 1987). In contrast, the imbricated and tapered ileal segment leading to an Indiana pouch is relatively easier to catheterize and can be used for orthotopic catheterizing diversion (Rowland et al, 1987). However, it may be difficult to obtain sufficient mesenteric length in some patients. The appendix can also be used as a neourethra, in which case mesenteric length should become less of a problem (Hubner and Pfluger, 1995).

Four general techniques have been employed to create a dependable, catheterizable continence zone. For right colon pouches, appendiceal tunneling procedures are the simplest of all to perform, because they use established surgical techniques already present in the urologic armamentarium. The in situ or transposed appendix is tunneled into the cecal taenia in a fashion similar to ureterocolonic anastomosis. Appendiceal continence mechanisms have been criticized for three general reasons. First, the appendix may be unavailable in some patients because of prior appendectomy. For those individuals, techniques have been developed that allow for the construction of a similar tube fashioned from ileum (Woodhouse and MacNeily, 1994) or from the wall of the right colon (Lampel et al, 1995a). Second, the appendiceal stump may be too short to reach the anterior abdominal wall or umbilicus while sufficient length is still maintained for tunneling. This criticism has been addressed by an operative variation described

Figure 98-3. A, The appendiceal stump is lengthened by the inclusion of a tubular portion of proximal cecum by the application of the gastrointestinal anastomosis (GIA) stapler to the terminal cecum. A window is made in the mesoappendix, and the blade of the GIA stapler is advanced through the window. This maneuver ensures that the blood supply is not inadvertently damaged. B, The added length is demonstrated. The appendix is rotated and implanted into the taenia; the cecal tube serves as the stoma. (From Burns MW, Mitchell ME. Tips on constructing the Mitrofanoff appendiceal stoma. *Contemp Urol* 1990;2:10-2.)

by Mitchell, in which the appendiceal stump can be lengthened by the inclusion of a tubular portion of proximal cecum (Burns and Mitchell, 1990) (Fig. 98-3). This lengthening procedure has the added advantage of allowing for a slightly larger stoma made of cecum that is less prone to stomal stenosis. Appendiceal continence mechanisms share the feature of allowing only small-diameter (14- to 16-Fr) catheters to be used for intermittent catheterization; the large amount of mucus produced by an intestinal reservoir is more easily emptied or irrigated with use of a 20- to 22-Fr catheter. We believe that these criticisms are more theoretic and that the appendiceal or pseudoappendiceal continence mechanism remains a very attractive and reliable continence mechanism.

The second major type of continence mechanism used in right colon pouches is the tapered and/or imbricated terminal ileum and ileocecal valve. Here again the technology is rather simple, with imbrication or plication of the ileocecal valve region along with tapering of the more proximal ileum in the fashion of a neourethra (Rowland et al, 1985; Lockhart, 1987; Bejany and Politano, 1988). These techniques afford a reliable continence mechanism.

One feature of right colon pouches that has been criticized is the loss of the ileocecal valve. Although this does result in an increased frequency of bowel movements for some patients in the short term, the majority will experience bowel regularity either through intestinal adaptation or with the use of pharmacologic therapy. However, some patients have developed rather striking diarrhea or steatorrhea after the loss of the ileocecal valve. This may be particularly true in pediatric patients in whom there is neurogenic bowel dysfunction (e.g., myelomeningocele).

The third surgical principle in constructing the continence mechanism is the use of the intussuscepted nipple valve or the flap valve, which avoids the need for intussusception. The creation of nipple valves is by far the most technologically demanding of all the continence mechanisms, and it is associated with the highest complication and reoperation rates. There exists a significant learning curve before the surgeon achieves reproducible and dependable results. For this reason, nipple valve construction should probably not be chosen by the surgeon carrying out occasional construction of continent pouches. Furthermore, it should be noted that in the past two decades we have seen the introduction of numerous modifications of the original technique of Kock for construction of a stable nipple valve. The singular reason for all of

these modifications is the rather disappointing long-term stability of the nipple valve in some patients. As a result, the group at the University of Southern California has developed the T pouch, which uses a flap valve (Stein et al, 1998). This procedure, which appears much simpler than the intussuscepted nipple valve, has been used to create both a continence and an antireflux mechanism. Nipple valve failure from slippage or valve effacement can be anticipated in 10% to 15% of cases even in the hands of the very best and experienced surgeons. In addition to slippage, nipple valves are subject to ischemic atrophy. When this occurs, a new nipple valve must be fashioned from a new bowel segment.

A final feature of stapled nipple valves is the potential for stone formation on exposed staples. This was greatly lessened by the omission of staples at the tip of the intussuscepted nipple valve, as suggested by Skinner and associates (1984). However, more proximal staples occasionally erode into the pouch and serve as a nidus for stone formation. These stones are usually manageable endoscopically with forceps extraction, or else with electrohydraulic or ultrasonic disintegration of the stone with subsequent forceps extraction of the staple. Although exposed staples may serve as a nidus for stone formation, continent urinary diversion in and of itself results in more urinary excretion of calcium, magnesium, and phosphate as compared with ileal conduit diversion (Terai et al, 1995). Thus, all patients undergoing continent diversion are at an increased risk for the formation of reservoir stones.

The fourth major technique of continence mechanism construction is the provision of a hydraulic valve, as in the Benchekroun nipple (Benchekroun, 1987). In this procedure a small bowel segment is isolated, with subsequent reversed intussusception that effectively apposes the mucosal surfaces of the segment. Tacking sutures are placed on a portion of the circumference of the intussuscepted segment to stabilize the nipple valve while allowing urine to flow freely between the leaves of apposed ileal mucosa. As the pouch fills, hydraulic pressure closes the leaves, thereby ensuring continence. The premise of this technique is that as the reservoir fills, the pressure within the valve would also increase, resulting in continence. Concerns regarding stomal stenosis, especially in children, and nipple destabilization have resulted in this procedure being largely abandoned (Sanda et al, 1996). As a result, it will not be discussed in this chapter.

General Procedural Methodology

During construction of the pouch, intraoperative testing for pouch integrity should always be performed. The continence mechanism is also tested for ease of catheterization as well as continence after the pouch construction has been completed. The pouch is filled with saline, the continence mechanism catheter is removed, and the pouch is compressed lightly to look for points of leakage as well as to test the continence mechanism for its ability to contain urine. **Thereafter the continence mechanism is catheterized to ensure ease of catheter passage. This is an extremely important and crucial maneuver because the inability to catheterize is a serious complication that will often result in the need for reoperation.** In general, all redundancy should be removed from the continence mechanism. It is often useful to secure the reservoir to the anterior abdominal wall in a manner that prevents the reservoir from migrating. This can prevent the development of a false passage or a kink, thereby facilitating catheterization.

Postoperatively, the larger-bore catheter used for drainage of the pouch should be irrigated at frequent intervals to prevent mucous obstruction. This can be performed at 4-hour intervals by simple irrigation with 45 to 50 mL of saline. Less frequent intervals of irrigation can be employed when the urine is totally diverted from the kidneys by means of long indwelling stents. It is essential that as soon as possible the patient be taught how to self-irrigate and that he or she understand the required regimen. This not only familiarizes the patients with the catheterization process, but also reduces the work burden on the nursing staff and allows for earlier discharge.

On the seventh postoperative day, a contrast study may be performed to ensure pouch integrity. If no leaks are noted, ureteral stents can be removed. When it has been ascertained that the ureteral anastomoses and pouch are intact, the suction drain is removed. The suprapubic tube (if employed) can also be removed at this time, or it can be left in place until the patient is confident with self-catheterization. The patient is taught to irrigate the tube traversing the continence mechanism at 4-hour intervals and whenever any episode of intra-abdominal pressure or discomfort is experienced. Once these procedures have been mastered and the patient is tolerating a regular diet, the patient can be discharged, usually at hospital days 6 to 8.

The following represents a summary of common patient questions and everyday solutions:

- *What kind of catheter do I use?* For nipple valves, a straight-ended 22- to 24-Fr tube; for ileocecal plication, a 20- to 22-Fr coudé-tipped catheter; and for appendiceal sphincters, a 14- to 16-Fr coudé-tipped catheter.
- *How do I carry my catheter?* In a zipper-locked bag that can be placed in a woman's purse or a man's coat pocket.
- *How do I clean the stoma before catheterizing in a public facility?* With a topical antiseptic wipe (e.g., with benzalkonium chloride), which can be purchased in individual foil-wrapped packets.
- *How do I lubricate the catheter?* By tearing off the end of an individual-use foil pack of water-soluble lubricant and inserting the tip of the catheter into the pack.
- *What do I do with the stoma after catheterizing?* Cover it with a bandage.
- *How do I clean my catheter after draining my pouch?* By rinsing with ordinary tap water through the inside channel and over the outside surface before replacing the catheter in its zipper-locked bag.

In the case of ileal pouches, pouch capacity will initially be low (150 mL). Therefore the frequency of catheterization will have to be significantly different in these individuals compared with those with right colon pouches in which initial comfortable capacities will be in excess of 300 mL. To ensure restful sleep, the smaller-capacity pouches may best be managed with indwelling catheterization during sleeping hours.

General Care

Because all patients with catheterized pouches will have chronic bacteriuria, the problem of antibiotic management should be discussed. Most authors would suggest that bacteriuria in the absence of symptomatology does not warrant antibiotic treatment (Skinner et al, 1987). The construction of an effective antireflux mechanism in these pouches may help protect against clinical episodes of pyelonephritis, in contrast to patients with freely refluxing conduits. Obviously, if clinical pyelonephritis does occur, antibiotic treatment should be instituted. Episodes of recurrent pyelonephritis should be evaluated with radiography of the pouch to diagnose failure of the antireflux mechanism or upper tract stone formation.

A condition termed "pouchitis" has been described that manifests with pain in the region of the pouch along with increased pouch contractility. It should be mentioned that this condition, although infrequent, may result in temporary failure of the continence mechanism because of the hypercontractility of the bowel segment employed for construction of the pouch. The patient typically has a history of sudden explosive discharge of urine through the continence mechanism (rather than dribbling incontinence), along with discomfort in the region of the pouch. Appropriate antibiotic therapy will usually result in resolution of these symptoms. It has been our experience that short courses of antibiotics are not usually successful in treating pouch infections. This may be because of the larger amount of foreign material in the form of mucus and sediment within intestinal pouches as opposed to the bladder. Intestinal crypts may also serve as bacterial sanctuaries. Therefore whenever a pouch infection is diagnosed, antibiotic therapy should be continued for at least 10 days. Pyelonephritis will, of course, require longer courses of therapy.

Urinary retention is an infrequent but serious occurrence in catheterizable pouches. It is most commonly seen with pouches whose continence mechanism consists of a nipple valve. In these circumstances, when the chimney of the nipple valve is not near the abdominal surface, the catheter may be misdirected into folds of bowel rather than into the nipple valve proper, resulting in urinary retention. **Pouch urinary retention represents a true emergency and the patient must seek immediate attention so that catheterization and drainage by experienced personnel can be achieved promptly.** The use of a coudé-tipped catheter may be helpful. Rarely, use of a flexible cystoscope will be necessary. After the immediate problem has been resolved by emptying the pouch, a catheter should be left indwelling for 3 to 5 days to allow the edema and trauma to the catheterization portal to resolve. Before discharge, the patient should be observed to successfully self-catheterize on multiple occasions. The appropriate angle of entry, which is highly individualized, should be taught to the patient until they are comfortable with the use of the new catheter. In fact, we prefer to routinely use coudé catheters with non-nipple valve pouches.

Intraperitoneal rupture of catheterizable pouches has been reported (Kristiansen et al, 1991; Thompson and Kursh, 1992; Watanabe et al, 1994). In general, these episodes are more common in the neurologic patient in whom sensation of pouch fullness may be less distinct (Hensle, personal communication, 1993; Mitchell, personal communication, 1993). Ruptures may also be associated with mild abdominal trauma, such as a fall. In general, these patients require immediate pouch decompression and radiographic pouch studies. For patients with large defects, surgical exploration and pouch repair are required. If the amount of urinary extravasation is small and the patient does not have evidence of peritonitis, catheter drainage and antibiotic administration may suffice in treating an intraperitoneal rupture. Patients managed with this conservative approach require careful monitoring. If there is any sign of progressive peritonitis, surgical exploration and repair are imperative. We have successfully employed this nonoperative approach on patients with ruptured right colon pouches.

Continent Ileal Reservoir (Kock Pouch)

This operation was first reported for use in urinary diversion by Kock and associates in 1982 (Kock et al, 1982). This report was singularly responsible for the renewed interest in continent diversion procedures at that time. An outgrowth of the Kock procedure for continent ileostomy (Kock, 1971), the Kock pouch combined reasonably dependable techniques for ensuring urinary continence and preventing reflux to the upper urinary tracts (nipple valves) with carefully refashioned bowel that provided a low-pressure urinary reservoir. This procedure and the similarly constructed T pouch are the only catheterizable continent diversions that preserve the ileocecal valve. Skinner and his coworkers (Skinner et al, 1989; Skinner, 1992) have carefully studied and improved the technique over the years while amassing prodigious experience with the operation and its variants. The high complication rate and the technical difficulties involved with constructing this reservoir have resulted in the procedure being abandoned by most individuals. As a result, this procedure is not discussed further in this edition. Those interested in a more detailed description should refer to our chapter in previous editions of this text. However, the construction of a Kock limb remains an important procedure for use in repairing failed continence or reflux mechanisms, and as such is described in more detail. It is Skinner's operative description that is followed closely in this chapter.

Procedure. A 15- to 20-cm length of ileum is selected for creating the intussuscepted nipple valve. The proximal 10 cm serves as the valve, and the distal 5 to 10 cm serves as the patch (Fig. 98-4A). The distal length is chosen based on the volume lost after resection of the failed mechanism. Only 5 cm is necessary for the patch, but on some occasions the reservoir itself may require augmentation. The middle 6 to 8 cm of the 10-cm segment is denuded of mesentery by electrocoagulation. An Allis or Babcock clamp is advanced into the ileal terminus, grasping the full thickness of the intussusceptum and inverting the ileum into the pouch (Fig. 98-4B). Using the TA-55 stapler, three rows of 4.8-mm staples are applied to the intussuscepted nipple valve (Fig. 98-4C). The distal six staples from each cartridge are removed before staple application to ensure that the tip of the valve is free of staples. Most authors suggest that the pin of the stapling instrument should always be kept in place so that staple misalignment does not occur. This will result in a pinhole puncture site at the base of the nipple valve that should be oversewn with absorbable suture material to prevent fistula formation after staple application is complete. The nipple valve is then fixed to the back wall of the patch by one of two stapling techniques (Skinner et al, 1984). A small buttonhole may be made in the back wall of the ileal plate so that the anvil of the stapler can be passed through the buttonhole and advanced into the nipple valve before application of the fourth row of staples (Fig. 98-4D). If this is carried out, the buttonhole is oversewn afterward with absorbable material. Alternatively, the anvil of the stapler can be directed between the two leaves of the intussusciens and the fourth row of staples used to fix the inner leaf of the nipple valve to the pouch wall (Fig. 98-4E).

Some authors, including Skinner and coworkers (1989), suggest the use of an absorbable mesh collar to anchor the base of the nipple valve. If a collar is used, a 2.5-cm wide strip of absorbable mesh is placed through an additional window of Deaver at the base of the nipple valve. The mesh strip is fashioned into a collar and sewn to the base of the patch with seromuscular sutures of absorbable material (Fig. 98-4F and G). The patch is then sewn to the reservoir.

Double T Pouch

As indicated earlier, many surgeons have abandoned the Kock pouch owing largely to the technical difficulties of creating the continence and antireflux mechanisms and the high complication rates associated with them. This should not be viewed as a condemnation of the pioneering work of Kock and his associates. Without

their initial efforts, many of the procedures described in this chapter would never have come into being. Rather, this represents the natural evolution of surgical techniques.

The group at the University of Southern California modified a technique described by Abol-Enein and Ghoneim (1993, 1994) to create a novel continence mechanism created entirely from ileum (Bochner et al, 1988). Abol-Enein and Ghoneim described a technique that created an extramural serosal tunnel into which the ureters were implanted. This extramural trough created a pseudo-tunnel that prevents reflux but in theory is associated with a lower risk of obstruction than the Goodwin (1958), Leadbetter and Leadbetter (1961), or LeDuc and colleagues (1987) techniques of direct transmural ureteral implantation. Stein and colleagues (1998) first reported on the use in a neobladder of a tapered ileal segment implanted into a serosal trough as the antireflux mechanism. In 1999 they reported on their adaptation of the technique to the ileal-anal reservoir. Also in 1999 they presented their early experience with a double T pouch as a replacement for the Kock pouch at the meeting of the American Urological Association (Stein et al, 1999a), and they published their findings in 2001 (Stein and Skinner, 2001). It is their technique that is presented in this section.

Procedure. A 70-cm segment of terminal ileum is isolated 15 to 20 cm from the ileocecal valve at the line of Treves. The proximal isoperistaltic 10- to 12-cm segment is isolated and will serve as the antireflux mechanism. The distal 12- to 15-cm segment is isolated and rotated in an antiperistaltic fashion and will create the cutaneous continence mechanism (Fig. 98-5A and B). A short 2- to 3-cm mesenteric incision is made to isolate the proximal limb, and a 4-cm incision is made for the distal limb, thereby preserving the major vascular arches. The proximal and distal segments can vary in length, depending on ureteral length and the thickness of the anterior abdominal wall. The middle 44 cm of ileum is folded in a W with each limb measuring 11 cm.

The afferent antireflux mechanism is created by opening the windows of Deaver between the vascular arcades along the distal 3 to 4 cm. The efferent continence mechanism is created by opening the proximal 7 to 8 cm of vascular arcades (antiperistaltic) (Fig. 98-5C). One-fourth-inch Penrose drains are then placed in each window of Deaver to facilitate the passage of the 3-0 silk horizontal mattress sutures that are used to approximate the serosa of the corresponding 11-cm limbs of the W (Fig. 98-5D). The 3- to 4-cm anchored portion of the proximal limb is then tapered over a 30-Fr catheter, and the 7- to 8-cm anchored portion of the efferent limb is tapered over a 16-Fr catheter. In both instances, tapering is performed with a gastrointestinal anastomosis (GIA) stapler (the staples will not be in contact with urine). Care must be taken in the efferent limb to create a gradual taper so that the catheter does not hit a false cul-de-sac (Fig. 98-5E). The portions of the 11-cm W limbs not forming the troughs are then sutured together with a running 3-0 polyglycolic acid (PGA) suture. The bowel is now incised along its antimesenteric border in the portion where the serosal trough exists and in close proximity to the medial PGA suture lines when beyond the two limbs (Fig. 98-5F). The incised mucosa is then closed in two layers with a running suture of 3-0 PGA. The incised intestinal flaps (antimesenteric incision) are then sutured to each ostium with interrupted sutures of 3-0 PGA, and the two ileal flaps are sutured over each segment with a running suture of 3-0 PGA (Fig. 98-5G). The reservoir is then closed side to side in two layers with 3-0 PGA, thereby completing its construction (Fig. 98-5H and I). The ureters are anastomosed end to side over stents to the proximal limb, which has been closed with a running absorbable Parker-Kerr suture. The efferent limb is then brought to the abdominal wall stoma site, and redundant ileum is resected. The stoma is then matured with the reservoir lying immediately adjacent to the anterior abdominal wall.

Postoperative Care and Comments. Postoperative care is similar to that for any continent reservoir. Stein and colleagues initially reported on 9 patients, 7 of whom could be evaluated for continence and long-term complications and 2 of whom died of disease during follow-up (Stein et al, 1999b). All 7 patients achieved

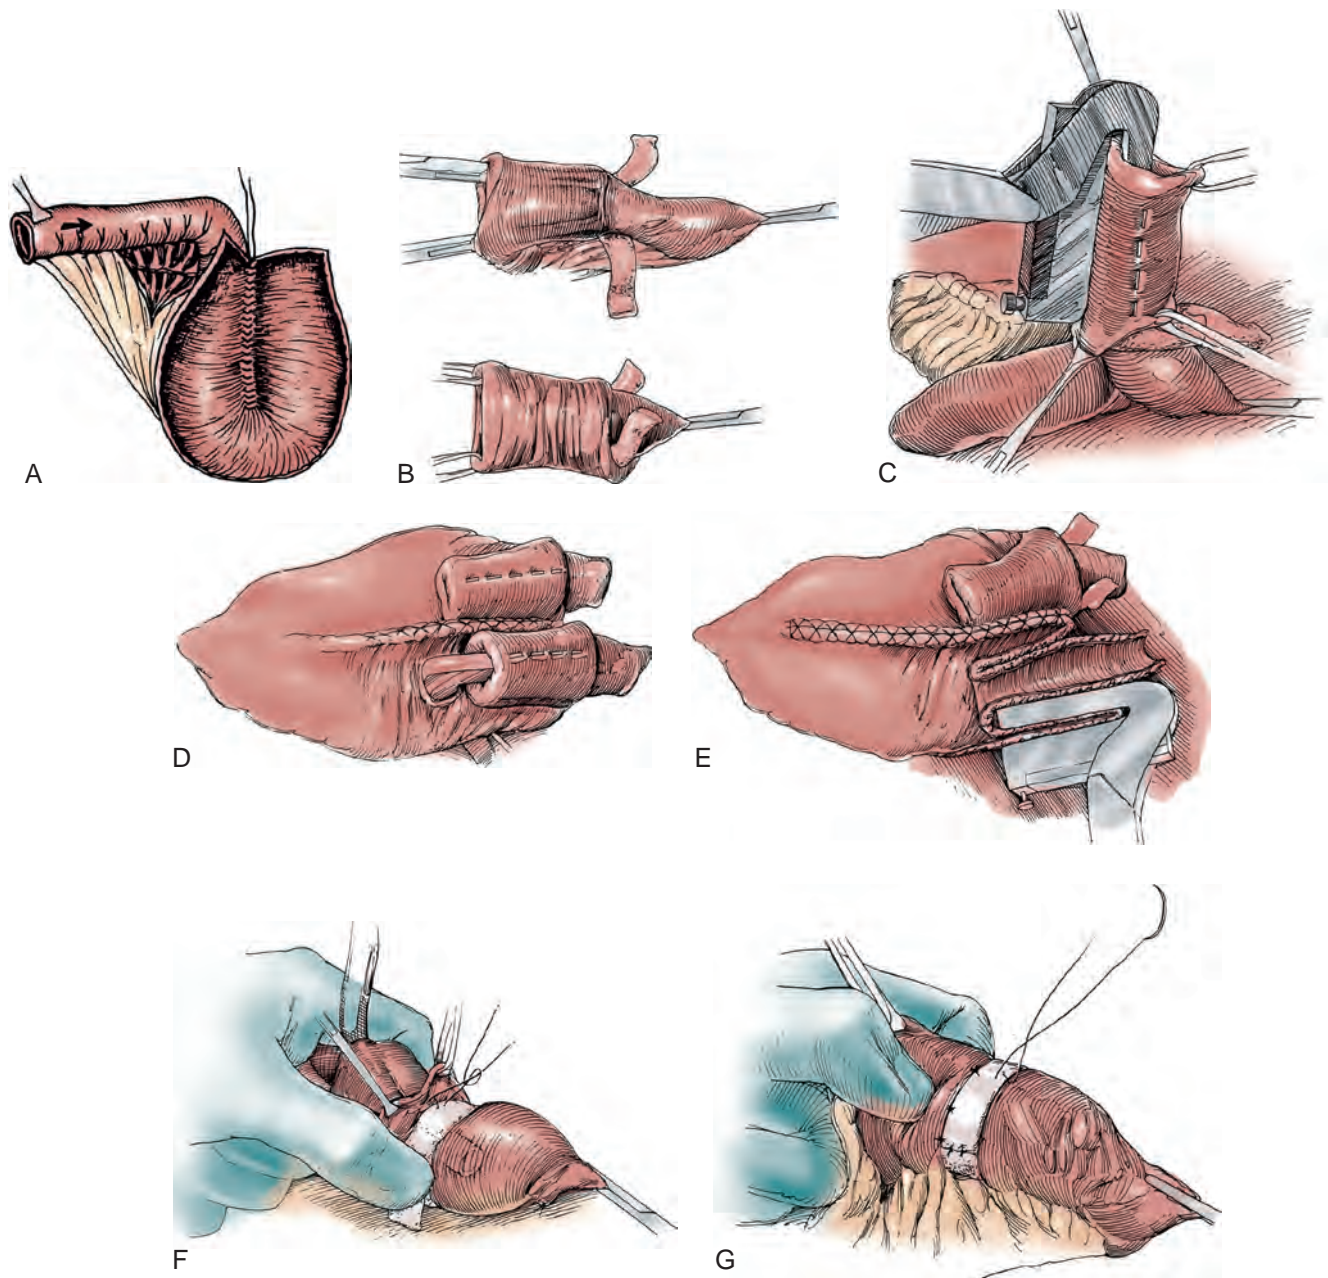

Figure 98-4. A, A 15-cm segment of terminal ileum is isolated and opened along its antimesenteric wall. The proximal 10 cm will serve as the continent intussusception, and the distal 5 to 10 cm as the patch. The size of the patch will vary according to the size of the excised segment. B, An Allis or Babcock clamp is advanced into the ileal terminus; the full thickness of the intussusciens is grasped, and it is prolapsed into the pouch. C, Three rows of 4.8-mm staples are applied to the intussuscepted nipple valve using the TA-55 stapler. D, A small buttonhole is made in the back wall of the ileal plate to allow the anvil of the TA-55 stapler to be passed through and advanced into the nipple valve. A fourth row of staples is applied. The figure shows two valve mechanisms, but in this instance there would be only one. E, The anvil of the stapler can be directed between the two leaves of the intussusciens and the fourth row of staples applied in this manner. Two valve mechanisms are shown but in this instance there would be only one. F, A 2.5-cm wide strip of absorbable mesh is placed through additional windows of Deaver at the base of each nipple valve. The mesh strips are fashioned into collars. G, The collars are sewn to the base of the pouch as well as to the ileal terminus with seromuscular sutures. (A, From Ghoneim MA, Lock NG, Lycke G, El-Din AB. An appliance-free, sphincter-controlled bladder substitute. *J Urol* 1987;138:1150–4. B to G, From Hinman F Jr: *Atlas of urologic surgery*. Philadelphia: Saunders; 1989.)

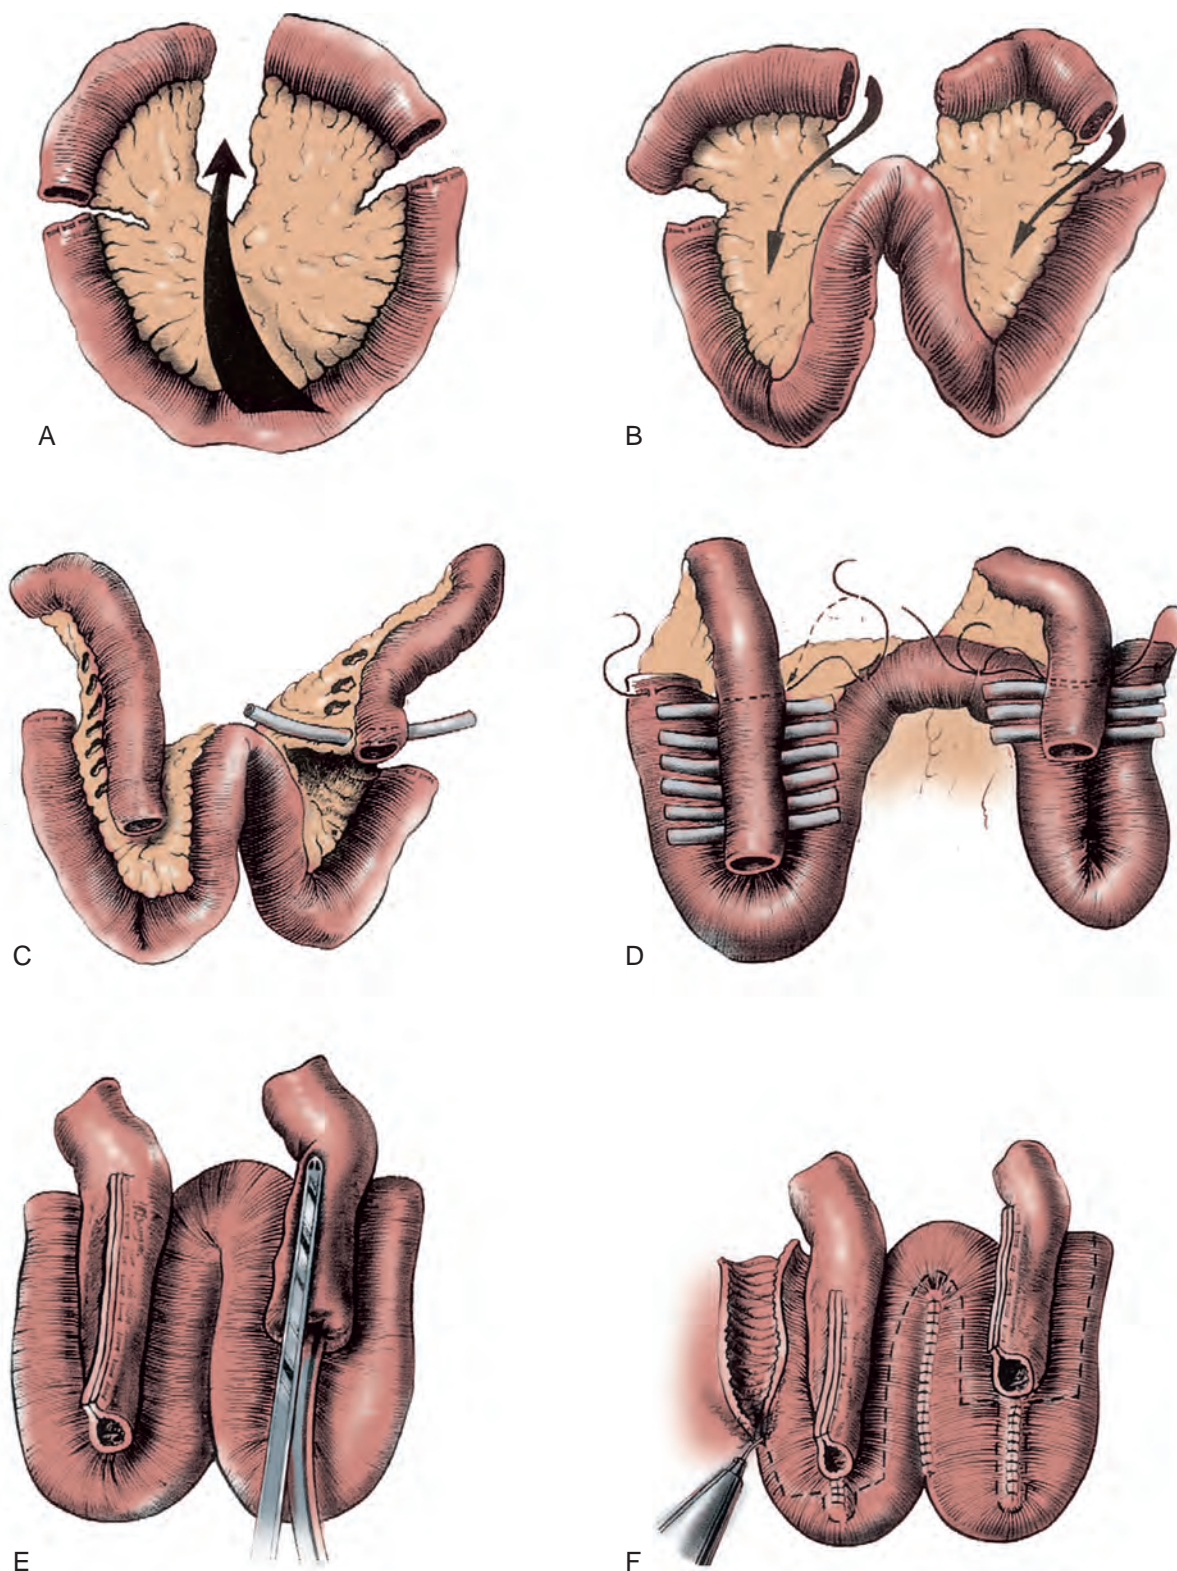

Figure 98-5. A, A 70-cm segment of terminal ileum is isolated 15 to 20 cm from the ileal cecal valve. B, A proximal 10-cm segment is isolated and rotated toward what will become the reservoir in an isoperistaltic direction. The distal 12 to 15 cm is rotated toward the reservoir in an antiperistaltic direction. C, The windows of Deaver are opened to allow the walls of the W reservoir to be apposed behind the valve mechanisms. Penrose drains are passed to guide suture passage. D, Horizontal mattress sutures of 3-0 silk are passed through each window. The distal continence mechanism is longer than the proximal antireflux mechanism. E, The proximal and distal mechanisms are tapered with a metal gastrointestinal anastomosis stapler. F, The bowel is incised along its antimesenteric border where it will overlie the two Ts. Distal to the Ts, the bowel is incised close to the approximated limbs of the reservoir.

Continued

Figure 98-5, cont'd G, The ostia of the valves are secured to the bowel wall with interrupted absorbable sutures. The two flaps of ileum are closed over the Ts with running absorbable sutures. H, The back wall of the reservoir is closed with running absorbable sutures. I, The lateral walls are folded medially and the construction is completed with running absorbable sutures. (From Stein JP, Buscarini M, DeFilippo RE, Skinner DG. Application of the T pouch as an ileo-anal reservoir. *J Urol* 1999;162:2052-3.)

immediate continence on catheter removal. However, 2 patients later became incontinent, with 1 requiring surgical revision. None of the 9 patients experienced an early postoperative complication. One patient developed a reservoir stone 9 months after surgery that was removed endoscopically without sequelae. Pouch capacity was excellent: 400 to 700 mL (average 500 mL). There was no radiographic evidence of reflux in any patient, and there was no upper tract deterioration. This operative procedure appears to have many advantages over the Kock pouch, and good long-term continence results have been reported. Marino and colleagues (2002) reported on 18 patients with 1-year follow-up with 100% daytime and nighttime continence and no delayed complications. Seifert and colleagues (2008) recently published their results on 19 patients who underwent ileal double T pouch construction between 1998 and 2006. Five patients (26%) had complications related to the diversion, some of which required surgical revision. Three patients (16%), all of whom had a body mass index exceeding 30, developed necrosis of the efferent loop and subsequent cutaneous fistulae. Sixteen (84%) eventually developed both daytime and nighttime continence. Although mild acidosis was common in this group, no

urinary reflux was detected, and no patients had significant upper tract deterioration or pyelonephritis.

Mainz Pouch I

The catheterizable Mainz pouch has undergone considerable modification over the years (Thüroff et al, 1985, 1988; Stein et al, 1995; Lampel et al, 1996; Gerharz et al, 1997; Thüroff et al, 2010). The main impetus for these changes has been the difficulty encountered with the nipple valve mechanism. The operative technique has now been modified to use the intact ileocecal valve as a means of further stabilizing the intussusception (Thüroff et al, 1988). This procedure is described here without further reference to earlier prototypes.

Procedure. The catheterizable Mainz pouch varies somewhat from the orthotopic, voiding Mainz pouch. First, a longer segment of bowel is used. A 10- to 15-cm portion of cecum and ascending colon is isolated along with two separate, equally sized limbs of distal ileum and an additional portion of ileum measuring 20 cm (Fig. 98-6A). The entire colon and distal segments of ileum are

Figure 98-6. A, A 10- to 15-cm portion of cecum and ascending colon is isolated along with two separate equal-sized limbs of distal ileum and an additional portion of ileum measuring 20 cm. B, A portion of the intact proximal ileal terminus is freed of its mesentery for a distance of 6 to 8 cm. C, The intact ileum is intussuscepted, and two rows of staples are taken on the intussusciens itself. D, The intussusciens is led through the intact ileocecal valve, and a third row of staples is taken to stabilize the nipple valve to the ileocecal valve. E, A fourth row of staples is taken inferiorly, securing the inner leaf of the intussusception to the ileal wall. F, A button of skin is removed from the depth of the umbilical funnel, and the ileal terminus is directed through this buttonhole. Excess ileal length is resected and ileum is sutured at the depth of the umbilical funnel. (A, From Thüroff JW, Alken P, Hohenfellner R. The Mainz pouch [mixed augmentation with ileum 'n' cecum] for bladder augmentation and continent diversion. In: King LR, Stone AR, Webster GD, editors. *Bladder reconstruction and continent urinary diversion*. Chicago: Year Book; 1987. p. 252; B to F, From Thüroff JW, Alken P, Riedmiller H, et al. 100 cases of Mainz pouch: continuing experience and evolution. *J Urol* 1988;140:283-8.)

spatulated, taking care to preserve the ileocecal valve. These three bowel segments are folded in the form of an incomplete W, and their posterior aspects are sutured to one another to form a broad posterior plate (Fig. 98-6B). A portion of the intact proximal ileal terminus is freed of its mesentery for a distance of 6 to 8 cm, and intussusception of the segment is achieved. Two rows of staples are applied on the intussusceptum itself (Fig. 98-6C). Thereafter, the intussusciens is led through the intact ileocecal valve and a third row of staples is applied to stabilize the nipple valve to the ileocecal valve (Fig. 98-6D). Finally, a fourth row of staples is applied inferiorly, securing the inner leaf of the intussusception to the ileal wall (Fig. 98-6E).

Ureterocolonic anastomoses are created at the apex of the reservoir, which is then folded on itself in a side-to-side fashion to complete pouch construction. The entire pouch is rotated cephalad so as to bring the ileal terminus to the region of the umbilicus. A small button of skin is removed from the depth of the umbilical funnel, and the ileal terminus is directed through this buttonhole (Fig. 98-6F). The pouch is secured to the posterior fascia with interrupted absorbable sutures, and the ileal terminus is sewn similarly to anterior fascia. Excess ileal length is resected, and the ileum is sutured at the depth of the umbilical funnel with interrupted absorbable sutures.

Postoperative Care and Comments. No specific differences in postoperative care or complications associated with the Mainz pouch need to be addressed. Initial pouch capacities are higher than with the Kock or T pouch. Final mean capacity averaging over 600 mL has been reported. Pouch pressures are 23 cm H₂O at half capacity and 31 cm H₂O when the pouch is full. Contraction waves beginning at 50% pouch fullness can be recorded at an amplitude of 12 cm H₂O. Thus, this pouch seems to produce a reasonably low-pressure urinary reservoir, although the pressures are not as low as those achieved with the use of small bowel alone.

The 10- and 12-year experiences with the Mainz pouch and the variations created by its developers have been described (Stein et al, 1995; Lampel et al, 1996). From 1983 to 1994, 440 patients underwent a Mainz I operation in two urology departments, Mainz and Wuppertal. Continence mechanisms varied: In 146 patients the appendix was used as the continence mechanism; in 270 patients the intussuscepted nipple was used as the continent stoma; in 14 patients a submucosal, seromuscular bowel flap was used; and in 10 patients a submucosal full-thickness bowel flap was used. The early complication rate was 12% and included mechanical ileus requiring open revision in 9 patients (1.6%), pouch leakage requiring revision in 5 patients (0.9%), wound dehiscence in 4 patients (0.7%), and fatal pulmonary emboli in 4 patients (0.7%).

The late complication rate was 37% and was predominantly attributable to the pouch. Stomal failure requiring open revision occurred in 45 patients (8%) and was directly related to the continence mechanism. Only 2 of 146 patients (1.4%) with an appendiceal continence mechanism were incontinent, but stomal stenosis occurred in 21%. The developers of this procedure were innovative in their attempts to bring the incontinence rate down to an acceptable level. To this end they tried multiple techniques, with variable success: an alloplastic stoma (4 of 4 incontinent); sutured intussusception (8 of 8 incontinent); stapled intussusception (5 of 22, 23% incontinent); and stapled ileocecal intussusception (10 of 204, 4.9% incontinent). The stapled ileocecal intussusception described previously is the current recommendation, and the long-term incontinence rate among the patients undergoing the stapled nipple valves was reduced to 10%. Other late complications included the need for ureteral reimplantation in 28 patients (4.9%), and stomal stenosis in 29 patients with an ileal nipple (11.7%) and in 17 patients with an appendiceal stoma (14.7%).

Calculus formation in the pouch occurred in 38 patients (6.8%), resulting in 36 percutaneous procedures. Despite the loss of the terminal ileum, no significant decrease in serum vitamin B₁₂ levels has been reported, and no patient has developed macrocytic anemia or neurologic symptoms. However, 25% of patients are on oral alkalinization to avoid metabolic acidosis.

Since the inception of this procedure, the overall complication rate has been considered high (31%). However, as [Stein and associates \(1995\)](#) pointed out, 50% of the complications were manageable with percutaneous techniques. In addition, since 1988 the incontinence rate has been only 3.2%, and less than 2% in patients with an appendiceal mechanism.

[Gerharz and associates \(1997\)](#) from Marburg, Germany, reported their single-institution experience with the Mainz I ileocecal pouch. From 1990 to 1996, 202 consecutive patients underwent continent diversion, 96 with a submucosally embedded in situ appendix and 106 with an intussuscepted ileal nipple. All patients had an umbilical stoma. In 172 of 200 patients (86%), no stomal complications occurred. In 17 of 96 patients (18%) with an appendiceal stoma, 23 revisions were performed for stomal stenosis. In contrast, only 13 of 106 patients (12%) with an intussuscepted ileal nipple developed problems with their stoma. However, these patients required more invasive, major procedures for correction, whereas those with an appendiceal stenosis could usually undergo repair with a minor

procedure. Three patients with an ileal nipple (3%) developed pouch calculi, whereas none of the patients with an appendiceal continence mechanism developed stones. As a result, [Gerharz and colleagues \(1997\)](#) concluded that the appendix, when available, should be the intestinal continence mechanism of choice.

We share the enthusiasm for the use of the appendix as a continence mechanism. In our experience this technique has also been reliable and easy to perform. It has been our tendency in constructing right colon pouches involving an appendiceal continence mechanism to use the entire right colon inclusive of the hepatic flexure to form the reservoir, thereby preserving more terminal ileum. This has the theoretic advantage of fewer metabolic complications, but the Mainz group has not reported significant metabolic problems.

The introduction of the more reliable appendiceal continence mechanism has greatly increased the acceptance of the Mainz I procedure. The Mainz group has also developed two new techniques for construction of a Mitrofanoff, or appendiceal, type of tube for use in patients whose appendix is either unsuitable or absent ([Lampel et al, 1995a, 1995b; Lampel and Thüroff, 1998](#)). Both techniques use a small-caliber conduit fashioned from the large intestine in the region of the cecum. One technique uses a full-thickness tube lined by mucosa ([Fig. 98-7](#)) and the other a seromuscular tube lined by serosa ([Fig. 98-8](#)). Both techniques appear to be successful, although the full-thickness tube was associated with a lower complication rate and a higher success rate in the initial report ([Lampel et al, 1995b](#)). With longer follow-up, [Lampel and coworkers \(1995b\)](#) have observed similar success rates with both tubes; 93% of the patients with a seromuscular tube (25 of 27) and 92% of the patients with a bowel wall tube (22 of 24) were continent day and night ([Lampel and Thüroff, 1998](#)). The authors believed that either tube was reliable and that each had its own unique advantages and disadvantages. In general, the full-thickness bowel wall tube was more adaptable owing to the ability to create a longer tube. However, this came at the expense of a more tenuous blood supply. The decreased distal blood supply might be improved by creating a wider base on the tube. This could, however, make taenial implantation more difficult. The seromuscular tube was equally reliable but could be anastomosed only to the umbilicus, owing to the short adit tube. Either tube was believed to be indicated as a continence mechanism in the Mainz I pouch when the appendix was not available or as a continence mechanism for reservoirs created from other large intestinal segments. Either

Figure 98-7. A to C, A full-thickness tube lined by mucosa is fashioned over an 18-Fr Foley catheter for tunneled reimplantation. The tube is closed with a running 3-0 absorbable suture. For longer tubes, we would advise a wider base to prevent distal ischemia. The continence mechanism is created by placing the tube into the adjacent taenial trough. (From [Lampel A, Hohenfellner M, Schultz-Lampel D, Thüroff JW. In-situ tunneled bowel flap tubes: 2 new techniques of a continent outlet for Mainz pouch cutaneous diversion. J Urol 1995;153:308-15.](#))

Figure 98-8. A to C, A 3- to 5-cm seromuscular tube denuded of mucosa and lined by serosa is fashioned for tunneled reimplantation. The tube is rolled over an 18-Fr Foley catheter. A mucosal window is opened at the base of the U, and the tube sutured to the mucosa with interrupted sutures. (From Lampel A, Hohenfellner M, Schultz-Lampel D, Thüroff JW. In situ tunneled bowel flap tubes: 2 new techniques of a continent outlet for Mainz pouch cutaneous diversion. *J Urol* 1995;153:308–15.)

technique could be used as a salvage procedure when another primary continence mechanism had failed.

Another novel [Mitrofanoff continence mechanism was described by Montie \(1997\)](#), who conceived of a procedure in which a 2- to 3-cm segment of terminal ileum is isolated on its blood supply ([Fig. 98-9A](#)). The width of the segment was chosen to correspond to the circumference of the tube to be created. Once isolated, the segment is opened near one of its mesenteric junctions to create a longitudinal reconfiguration ([Fig. 98-9B and C](#)). The tube is then closed with a running 3-0 absorbable suture ([Fig. 98-9D](#)). It can now be used for a Mitrofanoff implant. When longer tubes are necessary, two adjacent segments can be isolated, reconfigured, and joined together ([Fig. 98-9E and F](#)). Although the technique was originally described in dogs, [Montie \(1997\)](#) has used it in humans without complication. [Montie \(1997\)](#) reported on a high rate of stomal stenosis in dogs, but this may have been secondary to infrequent catheterizations. Stomal stenosis has not occurred in our limited series of patients. Other groups have used tapered ileum to create a tunneled access into the right colon ([Fig. 98-10](#)) ([Woodhouse and MacNeily, 1994](#); [Hampel](#)

[et al, 1995](#)). Using tapered ileum for this purpose has the advantage of a blood supply independent of the reservoir and no length restrictions while having the disadvantage of further limiting intestinal absorptive surface.

[Wiesner and colleagues \(2007\)](#) recently compared their long-term results in 458 patients who underwent Mainz I pouch construction. The anastomosis was made using a submucosal tunnel in 809 renal-ureteric units, and using a serosa-lined extramural tunnel in 74 units. At 17 months postoperatively they found a significantly higher occurrence of anastomotic obstruction in the submucosal tunnel group compared with the extramural group (7.3% vs. 4.1%, respectively). It is important to note that they found a much higher rate of obstruction in patients with previously dilated upper tracts (14%) or with a history of neurogenic bladder (17%). No significant deterioration of the upper tracts was identified.

In another comparison of patients with a Mainz I pouch, [Wiesner and colleagues \(2006\)](#) reported on 800 patients with almost 8 years of follow-up. Overall continence was approximately 93%. Stomal stenosis occurred in 23.5% of patients with a submucosally embedded in situ appendix, whereas stenosis was

Figure 98-9. A, A 2- to 3-cm segment of terminal ileum is isolated on its own blood supply. B and C, The tubular segment is opened approximately one fourth of the way up one side. This results in a well-vascularized rectangular plate. D, The rectangular tube is now closed over a catheter with a running absorbable suture. E and F, Two adjacent segments can be joined together to create one long tube. (From Monti PR, Lara RC, Dutra MA, et al. New techniques for construction of efferent conduits based on the Mitrofanoff principle. *Urology* 1997;49:112-5.)

Figure 98-10. A to C, Woodhouse tapered ileum. (From Woodhouse CR, MacNeily AE. The Mitrofanoff principle: expanding upon a versatile technique. *Br J Urol* 1994;74:447-53.)

reported in 15.3% of patients with an intussuscepted ileal nipple valve. Rates of calculi formation were the reverse: 10.8% incidence in patients with an ileal nipple valve but in only 5.6% of patients with an appendix stoma. Ischemic degeneration of the continence mechanism occurred almost three times more often in the appendiceal group.

Right Colon Pouches with Intussuscepted Terminal Ileum

Additional pouches using nipple valve technology for the continence mechanism include those right colon pouches in which intussusception of the terminal ileum and ileal cecal valve is employed. These are variations on the continent cecal reservoir

initially described by [Mansson \(1987\)](#) that employ an intact cecal segment. These three pouches are the UCLA pouch ([Raz, personal communication, 1989](#)), the Duke pouch ([Webster and King, 1987](#)), and Le Bag ([Light and Scardino, 1986](#)). These surgeries differ from one another by only a few features, mainly related to the technique employed for stabilizing the nipple valve. Unless the appendix is being used as a continence mechanism, appendectomy should be performed in all cases because an in situ appendix would serve as a nidus for infection and abscess formation.

These operations are described in detail in the prior edition of this text. Since that edition was published, no new modifications to these procedures have been reported, and they are not further described here. The reader is referred to the prior edition of this text for an in-depth description of these operations.

Indiana Pouch

The concept of using the buttressed ileocecal valve as a dependable continence mechanism that can withstand the trauma of intermittent catheterization was first reported by [Rowland and colleagues \(1987\)](#) from Indiana University. This operation, which involved the partial spatulation of the cecal segment and attachment of an ileal patch, represented major contributions to the original ileocecal reservoir as described by [Gilchrist and associates \(1950\)](#), in which the intact bowel reservoir was employed and no attempt was made to strengthen the ileocecal valve. Originally, strengthening the ileocecal valve consisted of making a double row of imbricating sutures to the entire ileal segment ([Rowland et al, 1985, 1987](#)). It soon became apparent that this was necessary only in the region of the ileocecal valve. "Neourethral" pressure profiles showed that the continence zone was confined to the region of the reconfigured ileocecal valve ([Bejany and Politano, 1988](#)). The remaining "neourethra" could be tapered and brought through an abdominal or perineal stoma. At Indiana University as well as other institutions it became clear that the concept of marsupializing only a portion of the ascending colon segment left enough peristaltic integrity in the cecal region to generate pressures sufficiently high to overcome the continence mechanism in some patients. A number of groups contributed to the concept of using the entire right colon or more, marsupializing the entire structure and refashioning it in a Heineke-Mikulicz configuration ([Lockhart, 1987](#); [Bejany and Politano, 1988](#); [Benson et al, 1988](#); [Rowland, personal communication, 1989](#)). These variations have been entitled the Florida pouch ([Lockhart, 1987](#)) and the University of Miami pouch ([Bejany and Politano, 1988](#)). However, they represent relatively minor variations on the theme of the Indiana pouch.

Procedure. The Indiana pouch in its present form involves isolating a segment of terminal ileum approximately 10 cm in length along with the entire right colon to the junction of the right and middle colic artery blood supplies ([Fig. 98-11A](#)). After bowel continuity is reestablished, appendectomy is performed and the appendiceal fat pad obscuring the inferior margin of the ileocecal junction is removed by cautery ([Fig. 98-11B](#)). The entire right colon is opened along its antimesenteric border, and ureteral-taenial implants are fashioned ([Fig. 98-11C](#)). The ileocecal junction is buttressed according to various reported techniques. With nonabsorbable sutures, interrupted Lembert sutures are taken over a distance of 3 to 4 cm in two rows for the double imbrication of the ileocecal valve as described at Indiana University ([Fig. 98-11D](#)). The second row of sutures should attempt to bring the opposite mesenteric edges of ileum together, usually over a 12- to 14-Fr catheter. These two rows of sutures should be placed approximately 8 mm from one another, and the initial suture in each row may be taken in a purse-string fashion around the cecal margin as well. Alternatively, the University of Miami group suggests placing purse-string sutures in the same ileal region ([Bejany and Politano, 1988](#)). Finally, the Tampa group suggests placement of apposing Lembert sutures on each side of the terminal ileum ([Fig. 98-11E](#)). The remaining ileum can be tapered over the catheter and excess ileum removed with a stapling technique ([Fig. 98-11F](#)).

It is important to carry out the imbrication while the cecal reservoir is still open ([Rowland, 1996](#)) so that the gradual closure of the ileocecal valve can be closely observed. The pouch is then closed in a Heineke-Mikulicz configuration with a running absorbable suture. Ureteral stents and a suprapubic tube are taken through a stab wound in the pouch and led through the right lower abdominal quadrant. The pouch is rotated so as to bring the ileal neourethra as close as possible to the selected stoma site. A fingerbreadth-wide skin button is transected along with a similar button from the anterior and posterior fascia. The ileal neourethra is advanced between bundles of the rectus muscle through the stoma and excess ileum is transected. The ileal edges are sewn to skin with interrupted sutures so as to create a flush stoma.

In addition to the differences in the technique of ileocecal valve imbrication, both the University of Miami and the Florida pouches differ in the amount of colon used. The entire ascending colon and the right third or half of the transverse colon is isolated along with 10 to 12 cm of ileum. The entire upper extremity of the large bowel is mobilized laterally in the fashion of an inverted U ([Fig. 98-12A](#)). The medial limbs of the U are sutured to each other after the bowel has been spatulated ([Fig. 98-12B](#)). The bowel plate is then closed side to side ([Fig. 98-12C](#)). This inverted-U closure, however, is exactly the same as a Heineke-Mikulicz reconfiguration.

There have been recent modifications to the Indiana reservoir that allow for more rapid construction and a lower complication rate ([Rowland, 1996](#)). The modifications incorporate the use of metal staples to create the efferent limb and absorbable staples to fashion the reservoir. The concept of using a metal GIA stapler to fashion the efferent limb was first introduced by [Bejany and Politano \(1988\)](#). [Carroll and Presti \(1992\)](#) reported on the urodynamic features of the stapled and plicated terminal ileum and found that the stapled limb performed equally well and was easier to construct. The use of absorbable staples to create this and other types of reservoirs is described later in the chapter.

Postoperative Care and Comments. The postoperative care of the patient with an Indiana pouch or its variants is not substantially different from that used in patients with other right colon catheterizable diversions. In early reports, Rowland recommended discharging the patient with the suprapubic tube in place until readmission to the hospital 3 weeks later for tube removal and instruction in self-catheterization. In the current medical climate, which places a premium on outpatient procedures, tube removal and catheterization instruction are now ambulatory procedures at most institutions, including Indiana University ([Bihrlé, 1997](#)).

Average pouch capacities of 400 to 500 mL have been reported by the Indiana group ([Rowland et al, 1987](#)). Combining the partially and totally spatulated bowel procedures, this group reports a reoperation rate of 26%. Overall continence rates of 93% have been achieved. Very elegant urodynamic studies were conducted in Indiana pouch variants by [Carroll and colleagues \(1989\)](#). They found only 86% of patients totally continent in a small series. However, their pouch capacities exceeded 650 mL, and peak contractions of 47 cm H₂O were recorded at capacity.

The last 81 patients operated on by Rowland underwent construction of a stapled efferent limb, and in the last 20 the reservoir was created with absorbable staples ([Rowland, 1996](#)). The results in this group of patients were extremely favorable. Early pouch-related complications occurred in only 3 patients (3.7%). Two patients experienced a pouch leak that was managed conservatively, and 1 patient required open revision of the efferent limb owing to difficulty with catheterization. Early complications not directly attributable to the pouch occurred in 7 patients (8.6%). Transient small bowel obstruction was the most common complication, occurring in 4 patients (4.9%). One patient developed a superficial wound infection, and 1 patient developed an abdominal abscess requiring surgery (1.2%). Late complications associated with the reservoir occurred in 23 patients (28.4%). Incontinence occurred in 6 patients (7.4%): in 5 patients it occurred secondary to high pouch pressures, and in the remaining patient it was caused by failure of the efferent limb. One of the former and the latter patient

Figure 98-11. A, A segment of terminal ileum approximately 10 cm in length along with the entire right colon is isolated. Modified Indiana University continent diversion. *Curr Surg Tech Urol* 1988;1:1–8. D and F, From Olsson CA. *Contemp Urol* 62–8, September 1989. E, From Lockhart J. Remodeled right colon: an alternative urinary reservoir. *J Urol* 1987;138:730–4.)

underwent reoperation. Three patients (3.7%) developed stomal stenosis, and 3 had parastomal hernias; all 6 underwent surgery. Pouch stones occurred in 3 patients: 1 underwent open removal, and 2 had endoscopic extraction. Acute pyelonephritis was seen in 4 patients (4.9%). The most common late complication not related to the pouch was small bowel obstruction; this was seen in 6 patients and was managed conservatively in 5. In summary, the early reoperation rate was 2.5% and the late reoperation rate 14.8%. At 1 year, daytime and nighttime dry intervals of 4 hours or longer were achieved in 98% of patients. Eighty-four percent of patients stated that they slept through the night without the need to awake for catheterization. Similarly excellent results in the last 150 patients, 50 with at least 2.5-year follow-up, were reported by Bihrlé (1997).

The Florida pouch has been performed in over 190 patients (Helal et al, 1993). In 165 patients and 326 ureters, no attempt was made to create a tunneled reimplantation. This approach was adopted owing to the high incidence of ureteral obstruction encountered in the first 30 ureters that were tunneled into a Florida pouch (43 patients, 13.3%). In the last 165 patients, 16 of 326 ureters (4.9%) developed primary obstruction and were treated by percutaneous balloon dilation, nephrectomy, or observation. Although no attempt was made to create an antirefluxing anastomosis, only 7.1% of the ureters implanted demonstrated reflux. All patients are being followed conservatively, and no renal deterioration has been demonstrated. In the initial 100 patients, a 7.2% reoperation rate was reported (Lockhart, 1987). Although hyperchloremia was noted in 70% of patients, only 4 patients (including those who had

Figure 98-13. A, The appendix is left attached to the cecum and buried into the adjacent cecal taenia by rolling it back onto itself. A wide tunnel is created that extends 5 to 6 cm from the base of the appendix. Windows are created in the mesoappendix between blood vessels. The appendix is folded cephalad into the tunnel (B), and seromuscular sutures are placed through the mesoappendix (C).

preexisting renal disease) required treatment. Reservoir capacities ranged from 400 to 1200 mL, and maximal reservoir pressures at capacity ranged from 18 to 55 cm H₂O (Lockhart, 1987). The reason why these authors experienced such a high incidence of ureteral obstruction with both nontunneled and tunneled ureteral colonic anastomoses is not clear. It is also surprising that only 23 of 326 ureters that were anastomosed end to side had reflux.

The University of Miami group has reported on its results in 75 patients. Early complications occurred in 19 patients (25%). Sixteen patients (21%) experienced late complications. The success rate of the ureterocolonic anastomosis was 90%, and total continence occurred in 98.6% of patients. Average pouch capacities were 750 mL or higher, and end filling pressures of 20 cm H₂O were reported. No patient required alkali therapy.

The Indiana pouch remains one of the most reliable of all catheterizable reservoirs. It is among the easiest to construct, and it has very low rates of short-term and intermediate-term (<2 years) complications (Rowland and Kropp, 1994; Navon et al, 1995). However, there is evidence that the rate of long-term complications, mainly involving the efferent limb in a modified version of the Indiana Pouch, may be higher (Holmes et al, 2002).

Penn Pouch

The Penn pouch was the first continent diversion employing the Mitrofanoff (1980) principle, in which the appendix served as the continence mechanism. As mentioned earlier, this operation enjoys the singular feature of affording a catheterizable continent diversion that can be performed using techniques already present in the urologic armamentarium.

Procedure. Two techniques of appendiceal continence mechanisms have been reported. Mitrofanoff reported excising the appendix with a button of cecum and reversing it on itself before tunneled reimplantation (Mitrofanoff, 1980; Duckett and Snyder, 1986). Alternatively, Riedmiller and coworkers (1990) left the appendix attached to the cecum and buried it into the adjacent taenia by rolling it back onto itself. A wide tunnel is created in the taenia extending 5 to 6 cm from the base of the appendix (Fig. 98-13). Windows are created in the mesoappendix between blood vessels. The appendix is folded cephalad into the tunnel, and seromuscular sutures are placed through the mesoappendix windows to complete the tunneling. The tip of the appendix is amputated and brought to the selected stoma site.

As described by Duckett and Snyder (1986), an ileocecal pouch is created by isolating a segment of cecum up to the junction of the ileocolic and middle colic blood supplies along with a similar length of terminal ileum. These two structures are marsupialized on the antimesenteric borders and sutured to one another in the form of a neotubularized pouch. The superior margin of the pouch is sutured in a transverse fashion (all sutures being of absorbable material). A button of cecum surrounding the origin of the appendix is circumcised, and the resulting cecal aperture is closed with running absorbable suture. The mesentery of the appendix is dissected carefully from the base of the cecum, thereby preserving its blood supply. The appendix is then reversed on itself so that the cecal button can reach the anterior abdominal wall and the tail of the appendix can be directed to the taenia of the colon (Fig. 98-14). The appendiceal tip is obliquely transected and may be spatulated, then a tunneled appendiceal-taenial implantation is carried out. If additional appendiceal length is required, the variation proposed by Burns and Mitchell (1990) of creating a tube from the base of the cecum can be employed (see Fig. 98-3). Instead of simple removal of the appendix with a button of cecum before preparing it for tunneling, the entire base of the cecum leading to the appendix can be resected in continuity with the appendix by the application of the GIA stapler. We have found it helpful to spatulate the distal tip of the appendix until it accommodates a catheter at least 12 to 14 Fr in diameter.

Postoperative Care and Comments. Although not shown in Duckett's surgical drawings, we suggest that a large-bore suprapubic tube be used to drain the pouch in the early postoperative interval. The size of the catheter admitted by the appendiceal stump is insufficient to allow for the passage of ureteral stents along with the 12- to 14-Fr catheter. In addition, safe irrigation of mucous debris is best managed by a larger-bore catheter.

Many groups have used the Mitrofanoff principle owing to the simplicity and reliability of the continence mechanism (Burger

et al, 1992; Bissada, 1993; Sumfest et al, 1993; Woodhouse and MacNeily, 1994; Hampel et al, 1995). Woodhouse and MacNeily (1994) reported on a series of 100 patients who underwent surgery from 1985 to 1993. Seven different catheterizable conduits into six different types of reservoir were used. Although these researchers found the Mitrofanoff principle to be versatile and associated with a high success rate (91% continence), the reoperation rate for tube complications was 33%.

Sumfest and associates (1993) affirmed the use of the appendix as the Mitrofanoff segment of choice. They reported a continence rate of 96%. In their hands, late complications included difficulty with catheterization in 10.6% and stomal stenosis in 19.1%.

Urodynamic properties and pouch capacities will be a function of the reservoir constructed. Most often, the appendix is used in situ (Burger et al, 1992), and the right colon, either alone or with associated terminal ileum (Mainz), serves as the reservoir. We have used the in situ appendix with a detubularized right colon reservoir and the native ileocecal valve as an antireflux mechanism (refluxing ureters implanted end to side into terminal ileum). In our hands this has resulted in an excellent success rate with no upper tract problems. The adequacy of the ileocecal valve as an antireflux mechanism was also reported by Alcini and associates (1994). In their series, however, the reservoir was not always detubularized and, as expected, upper tract complications ensued owing to high reservoir pressures. This procedure is uniquely capable of affording continent cutaneous diversion to the patient with short ureters because the terminal ileum can be left long enough to reach high into the retroperitoneum.

Gastric Pouches

Pioneering animal experimentation demonstrated the feasibility of employing stomach as a bladder patch or urinary reservoir (Sinaiko, 1956; Rudick et al, 1977; Leong, 1978). The use of the stomach to create a urinary reservoir has theoretic as well as real advantages (Adams et al, 1988). First, electrolyte reabsorption would be greatly diminished by use of this bowel segment in the reservoir. This would potentially make the stomach the selected reservoir for individuals with preexisting metabolic acidosis or renal insufficiency. Hyperchloremic acidosis would not be an anticipated problem; in fact, in addition to presenting a barrier against the absorption of chloride and ammonium, the gastric mucosa secretes chloride ions (Piser et al, 1987). Furthermore, in patients in whom shortening of the bowel may be expected to lead to some degree of malabsorption, the use of stomach is an attractive alternative. The acid pH of the urine may also reduce the risk of bacterial colonization. Finally, when the entire lower bowel has been irradiated, stomach tissue may provide healthy nonirradiated tissue for use in performing continent diversion. Given these theoretic advantages, a number of groups have initiated trials with gastric pouches and composite reservoirs in both pediatric (Adams et al, 1988) and adult (Lockhart et al, 1993; Austin et al, 1997) populations.

Procedure. A wedge-shaped segment of stomach with maximal width of 7 to 10 cm is fashioned from the greater curvature. Care is taken not to extend the wedge through to the lesser curvature to preserve vagal innervation and normal gastric emptying. The left gastroepiploic artery is preferentially used as the blood supply for the isolated gastric wedge, dividing the short gastric vessels from the more proximal artery up to the gastric fundus. Alternatively, if there is a problem with the left artery, the right gastroepiploic vessel may be employed, dividing the short gastric vessels to the level of the pylorus (Fig. 98-15A and B). The stomach is then closed according to the surgeon's preference. Neither gastroduodenostomy nor gastrojejunostomy is mandatory unless the antrum of the stomach has been used. The isolated wedge is refashioned into nearly a sphere by folding it back on itself and suturing the edges together with running absorbable material. Before pouch closure, one ureter is tunneled into the reservoir according to the surgeon's preferred antireflux technique. Contralaterally, proximal transureteroureterostomy is performed. The contralateral distal ureter is used to create

Figure 98-14. A segment of cecum up to the junction of the ileocolic and middle colic blood supplies along with a similar length of terminal ileum is isolated and marsupialized on the antimesenteric borders. A button of cecum surrounding the origin of the appendix is circumcised. The mesentery of the appendix is dissected carefully from the base of the cecum, preserving its blood supply. (From Duckett JW, Snyder HM 3rd. The Mitrofanoff principle in continent urinary reservoirs. *Semin Urol* 1987;5:55-62.)

Figure 98-15. A and B, A wedge-shaped segment of stomach whose greatest width is 7 to 10 cm is fashioned from the greater curvature. The left gastroepiploic artery is preferentially used as the blood supply for the isolated gastric wedge, by dividing the short gastric vessels up to the gastric fundus. Alternatively, if there is a problem with the left artery, the right gastroepiploic vessel may be employed. C, The isolated wedge is refashioned into nearly a sphere by folding it back on itself and suturing the edges together with running absorbable material. One ureter is tunneled into the reservoir. A proximal transureteroureterostomy is performed. The ipsilateral distal ureter is tunneled into the reservoir with its distal extent brought to the introitus to serve as a catheterization portal. R → L TUU, right-to-left transureteroureterostomy. (From Adams MC, Mitchell ME, Rink RC. Gastrocystoplasty: an alternative solution to the problem of urological reconstruction in the severely compromised patient. *J Urol* 1988;140:1152-6.)

Figure 98-16. A, An 11-cm segment of stomach is isolated on the right gastroepiploic blood supply using a GIA-90 stapler. Usually, two staplers are required. B, A 22-cm segment of ileum is then isolated, opened along its antimesenteric border, and refashioned in a U shape. C, The edges of the stomach are then sutured to edges of the ileum with a running absorbable suture of 2-0 polyglycolic acid. This completes the reservoir. The ureters are tunneled into the stomach, and a Mitrofanoff continence mechanism is created with a tapered segment of ileum. (From Lockhart JL, Davies R, Cox C, et al. The gastroileal pouch: an alternative continent urinary reservoir for patients with short bowel, acidosis and/or extensive pelvic radiation. *J Urol* 1993;150:46-51.)

the continence mechanism. The distal ureter is tunneled into the reservoir in a fashion similar to an appendiceal implant. The free portion of the ureter can then be brought to the skin or to the introitus (or urethral stump in males) to serve as a catheterization portal (Fig. 98-15C). Alternatively, the wedge of stomach can be

incorporated into a reservoir composed of detubularized ileum (Lockhart et al, 1993). In this procedure, an 11-cm segment of stomach is isolated on the right gastroepiploic blood supply (Fig. 98-16A). A 22-cm segment of ileum is then isolated, opened along its antimesenteric border, and refashioned in a U shape

(Fig. 98-16B). The edges of the stomach are then sutured to edges of the ileum with a running absorbable suture of 2-0 PGA. This completes the reservoir. The ureters are tunneled into the stomach, and a Mitrofanoff continence mechanism is created according to the preference of the surgeon. For example, the group from the University of South Florida employs a tapered segment of ileum (Fig. 98-16C).

Postoperative Care and Comments. Adams and associates (1988) reported mean pouch capacities of 245 mL and end filling pressures averaging 35 cm H₂O in a small patient sample. Combining their experience of gastric continent diversion and gastrocystoplasty, they reported minimal mucus production: only 3 of 13 patients required any irrigations, and the majority maintained sterile urine. Urine pH ranged from 4 to 7, but no introital ulceration from acid urine was reported. Three patients had minor elevations of serum gastrin, and none of the continent diversions required reoperation. Leong (1978) used similar concepts in gastric pouch construction and alluded to the creation of a voiding pouch created from stomach as well.

The construction of reservoirs entirely from stomach has not seen widespread acceptance. Rather, there has been greater use of stomach segments either for bladder augmentation or as a portion of a reservoir (composite) either alone or with an in situ catheterizable tube fashioned from a portion of the stomach (Gosalbez et al, 1994; Carr and Mitchell, 1996).

Gosalbez and colleagues (1994) reported on 15 patients who received a gastric tube as part of a composite gastric patch. Complications associated with the gastric patch and in situ tube included one each of early traumatic perforation of the tube, distal tube stenosis, and mucosal redundancy. Two of these patients required reoperation. Peristomal skin irritation from acid secretion occurred in 2 patients but was not considered severe. This is a more frequent complication in other reports and has resulted in skin breakdown in some instances.

Over a 10-year period from January 1985 to June 1995, Carr and Mitchell (1996) reported on the use of stomach in 12 patients. Seven had urinary reservoirs totally constructed from stomach, whereas 5 had composite reservoirs. They reported continence in all patients but that the continence mechanisms often required revision. Average bladder capacity was 309 mL, and average compliance was 12.9 mL/cm H₂O. When stomach is used as a bladder augment or as a portion of a neobladder, a dysuria and hematuria syndrome has been reported (Nguyen et al, 1993).

Austin and associates (1997) reported on nine adult patients with a mean follow-up of 54 months who underwent construction of a continent composite reservoir that was gastroileal in seven and gastrocolonic in two. All nine patients had either preexisting metabolic acidosis or a short bowel syndrome. All nine patients achieved electrolyte neutrality, and postoperative serum pH was significantly improved ($P < .01$). Three patients had a short-term serum gastrin elevation; the level returned to normal during follow-up. One patient developed skin ulceration at the stoma site.

The use of stomach has particular appeal in the pediatric population, in which the stomach's unique acid-base properties can be used not only to reconstruct but also to help correct the metabolic problems that are often associated with the need for pediatric urinary reconstruction (Carr and Mitchell, 1996). Although experience with use of the stomach remains small, its various unique intrinsic properties as a reservoir suggest that its use will continue in selected clinical situations.

QUALITY-OF-LIFE ASSESSMENTS

Extraordinarily few well-designed, prospectively conducted studies using validated instruments exist to assess quality of life after continent cutaneous urinary diversion. Multiple international studies have suggested an improved psychosocial adjustment of the patient undergoing continent urinary and fecal diversion compared with those patients with diversions requiring collecting appliances (Salter, 1992a, 1992b; Bjerre et al, 1995; Filipas et al, 1997; Hart

et al, 1999; McGuire et al, 2000). Although this may indeed be true, as exemplified by individuals with a conduit who desire conversion to a continent procedure, it is also true that many patients adjust well to wearing external appliances. The sense of body image is a remarkably personal and subjective parameter that varies greatly from patient to patient, and in fact quality of life after a conduit procedure appears to remain quite good (Gerharz et al, 2005). However, no randomized prospective trial has ever compared the quality of life after continent cutaneous diversion with that after either orthotopic continent diversion or incontinent urostomy, and there is no definitive conclusion that one form of urinary diversion is superior to any other (Porter and Penson, 2005). Of those studies performed, there appear to be common flaws in the study design and methods used that make any direct comparisons between continent and incontinent diversions difficult (Gerharz et al, 2005).

In general, most quality-of-life studies show similar results between patients undergoing ileal conduit and cutaneous continent diversion, with the latter being associated with improvements in stomal and urinary quality-of-life scores. In one of the few prospective studies to compare quality of life after continent cutaneous and ileal conduit diversion, Hardt and coworkers (2000) followed patients from the preoperative setting until 1 year after surgery. Using validated instruments tested for reliability, they found life satisfaction improved over time in patients with continent cutaneous diversion, whereas it worsened during the first year after ileal conduit construction. Using the Beck Depression Inventory and Profile of Mood States in adults, Boyd and colleagues (1987) found that patients choosing ileal conduit diversion had the lowest expectations of their quality of life. It is interesting to note that Boyd and colleagues found the highest overall satisfaction among patients undergoing conversion from ileal conduit to Kock cutaneous pouch diversion.

Mansson and associates (2002) found no difference in overall quality of life in men undergoing continent cutaneous diversion when compared with orthotopic neobladder using the Functional Assessment of Cancer Therapy (FACT)-Bladder and Hospital Anxiety and Depression Scale. In specific questions concerning intestinal, urinary, and sexual function, patients with cutaneous reservoirs experienced less difficulty with incontinence and emptied less frequently. Sexual function appeared better in patients undergoing orthotopic bladder substitution, likely because of urethral preservation. Large and colleagues (2010) used the validated FACT-Vanderbilt Cystectomy Index to compare quality of life measures in 92 women who underwent orthotopic neobladder compared with diversion with an Indiana pouch. With a median follow-up of at least 2 years, no significant difference was found in the physical, emotional, functional, or social measures of quality of life included in the instrument.

VARIATIONS IN OPERATIVE TECHNIQUE

Minimally Invasive Continent Cutaneous Diversion

With improvements in both laparoscopic- and robotic-assisted techniques, radical cystectomy is now commonly performed in many centers using these minimally invasive techniques. Many of the centers performing minimally invasive radical cystectomy have also reported performing orthotopic ileal neobladder procedures without converting to open techniques. However, there are very few reports of continent cutaneous diversions performed using minimally invasive techniques. Given the surgical complexity of these types of diversions, the vast majority of centers perform continent cutaneous diversions via standard open techniques. Türk and colleagues (2001) reported on an initial series of five patients who underwent radical cystectomy with bilateral pelvic lymphadenectomy and continent urinary diversion with use of a rectosigmoid pouch performed with an intracorporeal laparoscopic technique. Bilateral stented antireflux uterine reimplantation was used, and laparotomy was not performed. Operative time was 7.4 hours with minimal blood loss and a mean hospital stay of 10 days. No

intraoperative or postoperative complications were encountered. Intermediate-term oncologic and functional outcomes were reportedly similar to those achieved with an open approach (DeGer et al, 2004).

The complex nature of minimally invasive reconstructive surgery necessary in continent cutaneous diversion has limited these procedures to select centers. In addition, because of the prolonged time for return of postoperative bowel function, the benefits in hospital stay seen in other oncologic surgeries (e.g., laparoscopic nephrectomy) do not seem to exist when urinary diversion is performed.

Conduit Conversion to a Continent Reservoir

The major indication for conversion of a functioning conduit to a continent urinary reservoir is the patient's desire for improved quality of life. Pow-Sang and coworkers (1992) reported on conversion in 20 patients. Fifteen were converted from an ileal conduit, and 1 each from a cecal conduit, ureterosigmoidostomy, cutaneous ureterostomy, sigmoid conduit, and a suprapubic tube. In 14 of the 20 patients the conduit was discarded or used only as a patch to a colonic reservoir. It was observed that renal units that were obstructed preoperatively were associated with a 71% failure rate. Metabolic acidosis was seen in 15 (75%) but was believed to be mild. Pouch-related complications are, in general, a function of the reconstruction selected, and complication rates should not necessarily be higher in this setting. However, patient selection is very important in determining appropriate candidates for conversion.

We prefer to use the conduit in some form whenever possible. This strategy was supported in a report on two patients by Oesterling and Gearhart (1990). The use of an existing bowel segment has the potential to diminish metabolic sequelae and may result in a lower complication rate. The form of continent reconstruction chosen will have to depend on intraoperative findings, and no one procedure is more amenable than another. Before conversion is undertaken, the patient should be fully evaluated for disease recurrence, renal functional status, urinary anatomy, hydronephrosis, intestinal length, and intestinal health.

Pahernik and colleagues (2004) have described the long-term outcomes of conversion of 39 patients from conduit diversion to Mainz I pouch diversion. With a mean follow-up of 102 months the most common complications were stomal stenosis and pouch calculi. Long-term continence was achieved in 95% of patients.

Absorbable Stapling Techniques in Continent Urinary Diversion

The principle of bowel detubularization to increase reservoir capacity and diminish the effects of peristalsis is a fundamental principle of all contemporary continent urinary diversions. The process of detubularization and refashioning of the spatulated bowel segment consumes at least 1 hour of operating time and is by far the most time-consuming and tedious aspect of pouch construction. **The use of absorbable staples has substantially reduced the time required to fashion bowel reservoirs and has demonstrated short-term and long-term reliability with respect to reservoir integrity and volume.**

Bonney and Robinson (1990) first demonstrated the potential use of absorbable staplers to substitute for conventional suturing of bowel reservoirs. These authors used a bulky absorbable stapler (Polysorb staples in a TA Premium 55 stapler [U.S. Surgical Corp., Norwalk, CT]) to construct an S-pouch configuration in a canine ileal urinary pouch model. Although the same stapler was used in humans by Bonney and Robinson in 1992 and by Cummings in 1995, its clinical use was never widely adopted because the bulky staple configuration destroyed a significant portion of the bowel diameter, particularly when applied to the small intestine. The fact that up to 20 costly staple cartridges were required to complete the closure of a bowel reservoir further reduced the potential benefits of absorbable pouch construction.

A 75-mm GIA instrument (PolyGIA [U.S. Surgical Corp., Norwalk, CT]) that incorporates substantially smaller absorbable staples was made available for clinical use in 1992. The stapler delivers four rows of absorbable polylactic acid and PGA blend copolymer staples, dividing the bowel between the second and third rows. Thus, each staple line of the pouch has a double, staggered, stapled closure. This device has enabled both the refashioning and closure of bowel pouches to be performed with fewer staple applications and is strong and watertight. Finally, the width of bowel sacrificed with the new instrument is appreciably less than that with the older staple device. Several investigators have subsequently used the new "absorbable" GIA stapler to construct catheterizable pouches and neobladders (Olsson et al, 1993; Montie et al, 1994, 1995; Olsson and Kirsch, 1995). However, it is very important to note that the absorbable PolyGIA staples must not overlap because this will result in the failure of the staples to lock together. This is in direct contrast to metal staples, which are meant to overlap to create anastomotic integrity. As a result of the need to prevent overlap of absorbable staples, the reservoir construction procedures must be varied when such staples are used, as described later.

Surgical Techniques

Right Colon Pouch

In 1993, Olsson and colleagues described a technique using the absorbable GIA staplers to fully detubularize and refashion large bowel (Olsson et al, 1993). The technique of colon pouch construction described here incorporates the principles of bowel detubularization and refashioning using absorbable staplers in a simple "one-step" process.

The right colon and 10 cm of terminal ileum are mobilized by incising the peritoneum along the white line of Toldt and along the base of the mesentery and are isolated using metal GIA staplers (Fig. 98-17A). After bowel continuity has been restored with standard metal GIA and thoracoabdominal (TA) staplers, the distal staple line of the right colon is excised and the bowel lumen is irrigated to remove residual enteric contents. Using electrocautery, a small opening (2 cm) is created on the antimesenteric border of the cecum to fit the absorbable stapler. The distal open end of the colon is aligned with the cecostomy by folding the right colon on itself, as depicted in Figure 98-17B. The limbs of the absorbable GIA stapler are inserted into the distal open end and into the cecostomy, and the stapler is fired along the antimesenteric line of the apposed folded bowel (Fig. 98-17C). It is necessary to evert the bowel to continue subsequent staple applications. This may be achieved by placing Babcock clamps on each side of the distal staple line (Fig. 98-17D). A small incision at the junction of each staple line is made to prevent overlap of the absorbable staple rows and to allow for the next staple application. Because of this incision, there is often a short unstapled area at the junction between each application of the stapler, requiring one or two simple figure-of-eight sutures of 2-0 absorbable material at each of these points. The last staple application traverses the apex of the fold of bowel. In adults, three to four applications of the stapling device have been required to construct the right colon pouch, whereas in children two or three staple applications suffice. The appearance of the nearly completed pouch is illustrated in Figure 98-17E.

Once the generic right pouch has been fashioned, several options exist for ureteral anastomosis and formation of a sphincter mechanism. These maneuvers may be approached through the coalesced distal colon opening and cecostomy, which accesses the interior of the pouch (see Fig. 98-17E). The opening permits appropriate stent placement or inspection of a buttressed ileocecal valve. Any of the Mitrofanoff techniques described in conjunction with the Mainz I procedure can be employed. Likewise, the terminal ileum can be either stapled or pliated to create a continence mechanism. Once construction of a continence mechanism and ureteral anastomoses have been performed, the opening can be closed with a running 2-0 absorbable suture or the application of an absorbable TA stapler of appropriate length.

Figure 98-17. A, Isolation of colon and blood supply using metal gastrointestinal anastomosis staplers. B, Opening created in cecum and open end of colon to fit absorbable stapler. Bowel continuity restored between colon and ileum. C, Stapler activated along antimesenteric line and folded bowel. D, Inversion of bowel required to continue staple applications. E, Pouch inversion is complete. (From Olsson CA, Kirsch AJ, Whang MIS. Rapid construction of right colon pouch. *Curr Surg Tech Urol* 1993;6:1-8.)

Continent diversion procedures commonly employ the right colon or the cecum and terminal ileum. The array of right colon pouches that can be facilitated by this technique include all of the reservoirs described previously. Reservoirs using terminal ileum and cecum such as the Penn pouch and the Mainz pouch can also be fashioned in this manner.

Stapled Sigmoid Reservoir

The same stapling maneuvers can be applied to create a reservoir constructed from the sigmoid colon (Olsson and Kirsch, 1995). A portion of the sigmoid and descending colon measuring

approximately 35 cm is mobilized by incising the peritoneum along the white line of Toldt. Once mesenteric windows have been created, the segment of colon is isolated using metal GIA staplers (Fig. 98-18A). Restoration of bowel continuity is achieved with GIA, TA, or end-to-end anastomosis (EEA) staple devices.

Each of the metal stapled ends of the isolated colon are excised, and the bowel lumen is irrigated. The isolated sigmoid is folded on itself in a U configuration, aligning both open ends (Fig. 98-18B). The absorbable GIA stapler is inserted into the open bowel ends and fired along the antimesenteric line of the folded bowel (Fig. 98-18C). Following the procedure for bowel eversion as described earlier completes the reservoir. Again, usually two or three

Figure 98-18. A, Isolation of colon and blood supply using metal gastrointestinal anastomosis staplers. B, Sigmoid bowel folded in U shape. C, Stapler fired along antimesenteric border of folded sigmoid. D, Oversewing of superior open end completes pouch construction. (From Olsson CA, Kirsch AJ, Whang MIS. Rapid construction of right colon pouch. *Curr Surg Tech Urol* 1993;6:1-8.)

Figure 98-19. A, After closure of butt ends of reservoir with TA-55 stapler, enterotomy is made in dependent portion of first limb of W. Absorbable stapler is inserted through enterotomy and fired, creating common lumen between two adjacent limbs. Arrow indicates close-up of closure of enterotomy with TA-55 stapler. B, In middle limb of W, stapler is placed through enterotomy at apex and again common lumen is created. Staple lines are not directly apposing for their entire distance to avoid ischemia between adjacent staple lines. Arrow indicates site of enterotomy where urethroileal anastomosis will be performed. (From Pontes JE. *Genitourinary oncologic pelvic surgery*. New York: John Wiley; 1993.)

applications of the stapler are required to complete the pouch, cutting each staple line tip to avoid staple overlap.

After bowel reinversion, ureteral implants into the taenia can be carried out, using the residual colon opening to facilitate stent passage. These stents and a suprapubic tube are led through a separate stab wound in the pouch and brought through a lower abdominal wall stab incision. A continence mechanism employing one of the Mitrofanoff variations is then performed.

W-Stapled Reservoir

Montie and coworkers (1994) used the absorbable GIA stapler to construct ileal neobladders in patients undergoing cystoprostatectomy. A segment of ileum measuring 50 cm is divided with a standard metal GIA stapler 20 cm from the ileocecal valve. The terminal ends of each limb of the isolated ileal segment are closed with an absorbable TA-55 stapler, and the metal staple line is resected. The bowel is aligned in a W configuration, and an enterotomy is made 10 cm from each end (Fig. 98-19A). To facilitate closure of the enterotomy with a TA instrument (Fig. 98-19, inset), the enterotomy must be made midway between the mesentery and antimesenteric border. The absorbable GIA device is inserted through the enterotomy and is activated. This maneuver adjoins the two adjacent bowel segments. The enterotomy may be closed with the absorbable TA-55 instrument or running absorbable suture, completing the distal segment of the W. The middle and proximal segments are constructed similarly (Fig. 98-19B). Montie stresses that the segments of the W must be offset to avoid staple lines that overlap each other. Exceeding a 3- to 6-cm overlap may result in bowel ischemia.

Postoperative Care and Comments

In the first 50 adult patients to undergo our absorbable stapling technique in right colon pouch construction, with at least 7 years of follow-up there have been no complications attributable to absorbable staples. Similar results have been reported by Rowland

(1996). In the pediatric population, we have applied the absorbable stapler to continent urinary diversion, as well as to bladder augmentation (Hensle et al, 1995). In the first 18 children observed for up to 3 years, there have been no instances of pouch perforation or inadequate pouch capacity, and to date only one of the patients has developed a reservoir calculus.

Montie and colleagues (1994) used absorbable staplers to create W-stapled ileal neobladders in 25 patients. Ileal pouch construction was performed in approximately 20 minutes, and functional aspects were comparable to those of bowel reservoirs constructed by conventional suturing. Urodynamic evaluation at 6 months, however, documented a small-capacity reservoir requiring augmentation enterocystoplasty in 3 of 25 patients (12%). Montie and colleagues attributed this complication to either the size of the staples or reservoir fibrosis secondary to foreign body reaction. It is conceivable that a similar situation would arise when constructing a W-stapled T pouch.

We have used the absorbable stapler to construct both large and small bowel reservoirs. In our experience, colonic pouches appear better suited for construction with the absorbable stapler because of their relatively larger lumen. The introduction of stapling devices delivering still smaller staples and automatic staple line sealing devices may prevent the problems that occur when ileal pouches are constructed with current technology.

SUMMARY

In summary, continent urinary diversion is now an accepted part of the urologic surgical armamentarium. A wide array of surgical techniques exist to accomplish the desired goal of creating a continent, stomal free, nonrefluxing pouch. A paucity of long-term quality-of-life studies exists to compare outcomes between continent cutaneous urinary diversion and ileal conduit urinary diversion. Surgeons contemplating these forms of urinary diversion should familiarize themselves with several of the techniques and the management of the most common complications.

KEY POINTS

- Because the ability to self-catheterize is essential to the patient undergoing continent diversion, the patient must be assessed for the ability to care for himself or herself.
- Patients with multiple sclerosis, quadriplegic individuals, and very frail or mentally impaired patients will at some point in their lives require the care of members of the family or a visiting nurse, and such patients are viewed as poor candidates for any form of continent diversion.
- Renal and hepatic function must be reviewed carefully in the patient selected for continent diversion. The reabsorption and recirculation of urinary constituents and other metabolites require that liver function be normal and that serum creatinine levels be in the normal range, certainly below the level of 1.8 mg/dL.
- When the ureters are directed into the fecal stream, routine colonoscopy should also be performed. There have been isolated reports of malignancy developing earlier, and all patients developing gross or microscopic hematuria should be fully evaluated.
- Many studies from throughout the world have suggested an improved psychosocial adjustment of the patient undergoing continent urinary and fecal diversion compared with those patients with diversions requiring collecting appliances.
- Four general techniques have been employed to create a dependable, catheterizable continence zone. For right colon pouches, appendiceal techniques, pseudoappendiceal tubes fashioned from ileum or right colon, and ileocecal valve plication are adaptable. Appendiceal tunneling techniques are the simplest of all to perform in that they use established surgical techniques that are already in the urologic armamentarium.
- The second major type of continence mechanism used in right colon pouches is the tapered and/or imbricated terminal ileum and ileocecal valve. However, some patients have developed rather striking diarrhea and steatorrhea after the loss of the ileocecal valve. This may be particularly true in the pediatric patient.
- The third surgical principle used in constructing the continence mechanism is the use of the intussuscepted nipple valve or, more recently, the flap valve, which avoids the need for intussusception. The creation of nipple valves is the most technologically demanding of all the continence mechanisms and is associated with the highest complication rate.
- The fourth major technique of continence mechanism construction is the provision of a hydraulic valve, as in the Benckroun nipple. In this procedure, a small bowel segment is isolated and a reversed intussusception is used to appose the surfaces of the small bowel.
- Pouch urinary retention represents a true emergency, and the patient must seek immediate attention so that catheterization and drainage by experienced personnel can be achieved promptly.
- Because all patients with catheterized pouches will have chronic bacteriuria, the problem of antibiotic management should be discussed. Most authors would suggest that bacteriuria in the absence of symptomatology does not warrant antibiotic treatment.
- The concept of using the buttressed ileocecal valve as a dependable continence mechanism that can withstand the trauma of intermittent catheterization was first reported from Indiana University by Rowland and Mitchell (Rowland et al, 1987).
- The Indiana pouch remains one of the most reliable of all catheterizable reservoirs. It is among the easiest to construct, and it has very low short-term and long-term complications.
- The use of absorbable staplers has substantially reduced the time required to fashion bowel reservoirs and has demonstrated short-term and long-term reliability with respect to reservoir integrity and volume.
- It is anticipated that in the near future technologic advances in minimally invasive surgery will allow for the laparoscopic (robotic) construction of these reservoirs. These technologic advances will likely include automated suturing devices and biosealants.

Results and Complications of Orthotopic Urinary Diversion

HISTORY OF ORTHOTOPIC URINARY DIVERSION

Since the early 1900s, innovative surgeons have sought the best method to replace the original bladder when it must be removed because of either benign or malignant disease. The objective of bladder substitution is to allow volitional voiding through the urethra while eliminating the need for a cutaneous urinary stoma or intermittent catheterization.

Ureterosigmoidostomy is the oldest form of urinary diversion. The first reported urinary diversion into a segment of bowel was by [Simon in 1852](#). He attempted a ureterosigmoidostomy in an exstrophy patient by bringing the ureters into the rectum with the use of needles and suture to create a fistula. Although the patient died of sepsis 12 months later, this marked the first reported attempt at some form of urinary diversion ([Simon, 1852](#)). Over the following 100 years the evolution of urinary diversion was marked by a continued search for better methods and techniques to reconstruct the lower urinary tract. A number of technical modifications of the ureterosigmoidostomy ensued, particularly related to the ureteral implantation technique ([Hinman and Weyrauch, 1936](#)). The rates of obstruction and ascending pyelonephritis in patients with ureterosigmoidostomy were significantly reduced after introduction of an antireflux tunneled anastomosis of the ureter into the sigmoid colon ([Leadbetter, 1951](#); [Goodwin et al, 1953](#)).

Ureterosigmoidostomy remained the diversion of choice until the late 1950s, but long-term electrolyte imbalance, upper tract obstruction and infection, and secondary malignant neoplasms arising at the ureteral implantation site were observed ([Clarke and Leadbetter, 1955](#); [Wear and Barquin, 1973](#)). In 1950 [Bricker refined and popularized the ileal conduit form of urinary diversion, building on an original description by Zaayer in 1911 \(Zaayer, 1911; Bricker, 1950\)](#). The ileal conduit is a technically simple, reliable form of urinary diversion that became widely accepted and became the gold standard to which other types of urinary diversion were compared until the 1980s. It continues to be by far the most common form of urinary diversion performed throughout the world today for patients undergoing cystectomy.

Long-term complications with the Bricker ileal conduit started to come to light in the 1970s. Although problems with hyperchloremic metabolic acidosis and pyelonephritis were substantially less common than in patients with ureterosigmoidostomy, **late complications with the ileal conduit such as peristomal hernia, stomal stenosis, pyelonephritis, kidney stones, ureteral obstruction, and renal deterioration became more apparent with longer follow-up** ([Butcher et al, 1962](#); [Shapiro et al, 1975](#); [Middleton and Hendren, 1976](#); [Pitts and Muecke, 1979](#); [Sullivan et al, 1980](#); [Kouba et al, 2007](#); [Shimko et al, 2011](#)). These clinical sequelae

were thought to be related to the high-pressure reflux of infected urine or obstruction of the upper urinary tract. It was postulated that the addition of an antireflux technique to a conduit form of diversion could help diminish the problems of reflux and renal deterioration in these patients. In fact, animal experiments provided evidence to support the advantage of nonrefluxing colonic conduits over ileal conduits ([Richie et al, 1974](#)). Unfortunately, with longer follow-up, similar complications with nonrefluxing colon conduits were observed ([Morales and Golimbu, 1975](#); [Althausen et al, 1978](#); [Elder et al, 1979](#)).

One of the earliest continent cutaneous diversions in humans was described by [Gilchrist and colleagues in 1950](#). This form of urinary reconstruction incorporated a cecal reservoir with the ileocecal valve as the continence mechanism and the distal ileum as a catheterizable stoma ([Gilchrist et al, 1950](#)). However, this innovation attracted little attention at the time. The concept of a continent cutaneous diversion was subsequently reintroduced by [Kock and colleagues in 1982](#) with a technique that was originally developed for a continent ileostomy after colectomy for inflammatory bowel disease. It incorporated an intussuscepted nipple valve to maintain continence and avoid reflux. In animal experiments and then in humans, **Kock demonstrated the importance of complete detubularization of the bowel segment and the double-folding technique that creates the most spheric shape possible** ([Eckman et al, 1964](#); [Kock et al, 1982](#)). These concepts are the cornerstone of current cutaneous and orthotopic reservoirs. After Kock described his results in his initial 12 patients, Skinner began performing this diversion in adults undergoing cystectomy for bladder cancer in 1982. Although this form of urinary diversion required catheterization of an abdominal stoma, it eliminated the need for an external urostomy appliance. It was a popular concept for patients and referring physicians alike, and Skinner quickly amassed a large clinical experience with this type of continent cutaneous diversion ([Skinner et al, 1984, 1988](#)).

The biggest challenge in the development of continent cutaneous diversion has been the design of a reliable, durable, efferent continence mechanism that is easily catheterizable. A number of techniques have been described using large and small bowel and even stomach, with many ingenious continence mechanisms. However, stones, difficulty in catheterizing, peristomal hernias, and the development of leakage are potential problems with all of them, often necessitating open surgical revision ([Lieskovsky et al, 1987](#); [Rowland, 1995](#)). Today, several different reliable techniques are available to create a continent cutaneous urinary diversion, including the Indiana pouch and various other forms of right colon pouches. These forms of diversion can potentially offer an advantage to patients over an ileal conduit, but these operations remain technically challenging and are not widely used.

The concept of orthotopic diversion began even before Kock's continent cutaneous diversion. Tizzoni and Poggi were the first to experiment in a dog, transplanting the ureters into an isolated loop of ileum interposed between the ureters and the urethra. The dog was reportedly continent and subsequently underwent three successful pregnancies before dying 30 months postoperatively (Tizzoni and Poggi, 1888). Lemoine is credited with performing the first orthotopic reconstruction in a human subject. This patient initially underwent a cystectomy with ureterosigmoidostomy. Complications related to recurrent pyelonephritis led to undiversion in this patient; the rectal segment was isolated, transected, and anastomosed to the urethra, and the sigmoid colon was brought down and anastomosed to the anus (Lemoine, 1913).

In 1979, Camey and Le Duc reported their pioneering clinical experience with orthotopic substitution to the native urethra in male bladder cancer patients (Camey and Le Duc, 1979). The initial Camey diversion used an intact segment of ileum, resulting in a high-pressure reservoir. Subsequently the Camey II detubularized reservoir (Camey, 1990); Hautmann W-neobladder (Hautmann et al, 1988); "hemi-Kock" neobladder (Skinner et al, 1991); Studer pouch (Studer et al, 1989); extraserosal-lined ureteral tunnel (Abol-Enein and Ghoneim, 1993); T pouch (Stein et al, 1998b); stomach neobladder (Hauri, 1998); cecal and ileocecal neobladders (Light and Engelmann, 1986; Mansson and Colleen, 1990); and sigmoid reservoir (Reddy and Lange, 1987) have all been described. Many of these now have a large clinical experience with long-term follow-up demonstrating good renal preservation and continence results. Orthotopic diversion quickly surpassed continent cutaneous diversion in popularity for both patients and physicians, because it allows natural voiding, is simpler to construct, and is less likely to require revision surgery at a later date.

Initially these techniques were applied only to male patients because continence in women was believed to be dependent on an intact bladder neck and there was concern about higher local recurrence with the retained urethra. In the mid 1990s it was discovered through anatomic dissections and initial clinical experience that

women could remain continent with a low-pressure reservoir and preservation of only the urethra itself (Stein et al, 1994b; Borirakchanyavat et al, 1997; Colleselli et al, 1998). In addition, there were several careful pathologic studies of female cystectomy specimens showing that preservation of the urethra did not compromise oncologic efficacy provided the urethral margin was negative on intraoperative frozen section (Stein et al, 1995; Stenzl et al, 1995b; Maralani et al, 1997; Stein et al, 1998a).

Although the ideal bladder substitute remains to be developed, the orthotopic neobladder most closely resembles the original bladder in both location and function. This form of lower urinary tract reconstruction relies on the intact external rhabdosphincter continence mechanism, seldom requires intermittent catheterization, and avoids the difficulties associated with the efferent continence mechanism of continent cutaneous reservoirs. Voiding is accomplished by relaxation of the pelvic floor musculature (as in normal voiding) along with a concomitant increase in intra-abdominal pressure (Valsalva maneuver).

Orthotopic reconstruction has replaced the ileal conduit as the standard form of reconstruction in many centers of excellence worldwide. Hautmann and Paiss attempted to determine whether the option of a neobladder substitute stimulated the decisions of patient and physician toward an earlier cystectomy in patients with bladder cancer. They reported on a total of 213 men undergoing cystectomy for bladder malignant neoplasm, 135 patients with an ileal neobladder, and 78 with an ileal conduit diversion. The interval from the primary diagnosis was 11.8 months in the neobladder and 16.7 months in the conduit group. Five-year survival rates were significantly higher for all disease stages in the neobladder group than in the conduit group, and the authors concluded that the availability of ileal neobladder may decrease the physician's reluctance to perform cystectomy early in the disease process (Hautmann and Paiss, 1998).

The experience of urinary diversion at the Keck School of Medicine of the University of Southern California demonstrates the evolution of urinary diversion at that institution (Fig. 99-1).

Figure 99-1. Evolution of urinary diversion at the University of Southern California from 1971 to 2010. Orthotopic reconstruction was first applied to men in 1986 and to women in 1990, with a steady increase in the number of bladder substitutes since that time and a decline in the number of conduit forms of diversion during the same period. Recent increases in the percentage of older patients with more comorbidities have resulted in a slight increase in ileal conduit diversion.

Beginning in 1986, the number of orthotopic bladder substitutions performed dramatically increased to more than 75% of cystectomies, while the number of conduits and continent cutaneous diversions declined. Similar results occurred in Ulm, Germany and many other sites that embraced continent diversion as an alternative to ileal conduit. In eight other academic centers internationally, each with a large cystectomy experience, there is a very wide range in the rate of neobladder diversion in recent years, ranging from 6% to 51% (Hautmann et al, 2013). In a population-based study in the United States using the Nationwide Inpatient Sample database from 2001 to 2008, only 8% of cystectomy patients underwent continent urinary diversion, a rate that increased only to 20% even for patients under age 55 (Kim et al, 2013). In Sweden the national rate was 14% for all patients from 2003 to 2008 (Hautmann et al, 2013). In one high-volume academic center in the United States the rate of neobladder dropped dramatically from 47% to 21% over only a 5-year period from 2000 to 2005 (Lowrance et al, 2009).

The reasons behind this very wide variability are complex. Although surgeons point to differences in patient populations (e.g., increasing age, comorbidity, socioeconomic challenges), it is much more likely that which diversion is offered and/or recommended by specific physicians and institutions is heavily influenced by differences in surgeon philosophy and training, as well as misconceptions regarding results. Chang and colleagues have pointed out that trainees in most residency programs are exposed to few if any of these procedures (Chang et al, 2006). In addition, many cystectomies in the United States are performed by surgeons who do only a few such cases per year (Barbieri et al, 2007). In the United States there is also a lack of any economic incentive for the surgeon to learn or perform a potentially more complex operation (Skinner, 2011); in fact, a longer procedure is counterproductive from a financial perspective. The adoption of robotic techniques may be further aggravating this situation.

It is estimated that approximately 80% to 90% of male patients and 75% of female patients undergoing cystectomy are potential candidates for neobladder construction from a purely medical standpoint. In the series from Ulm, Germany, only 16% of the patients undergoing cystectomy had medical contraindications to orthotopic diversion, and another 2% refused (Hautmann et al, 2010). In another study examining the choice of urinary diversion in the context of a standardized preoperative counseling program, only 6% of patients who were eligible for a continent urinary diversion chose to undergo an ileal conduit for personal reasons (Ashley and Daneshmand, 2010). It is incumbent on the surgeon who is going to offer orthotopic diversion to understand the indications, surgical techniques, and principles of perioperative management to optimize outcomes.

KEY POINTS: HISTORIC EVOLUTION OF ORTHOTOPIC URINARY DIVERSION

- Historically, urinary diversion has developed along three paths: a conduit form of diversion, continent cutaneous diversion, and most recently orthotopic diversion.
- Long-term complications of the ileal and colon conduits include stomal stenosis, peristomal hernia, pyelonephritis, calculus formation, ureteral obstruction, and renal deterioration.
- The major long-term problems with continent cutaneous diversion relate to malfunction of the efferent continence mechanism, and open surgical revision is often required.
- The orthotopic neobladder relies on the rhabdosphincter for continence; most patients are continent and able to void to completion without the need for intermittent catheterization.
- Female patients with an intact functioning urethra are also potential candidates for orthotopic diversion.

BASIC PRINCIPLES OF CONTINENT ORTHOTOPIC URINARY DIVERSION

Many methods for construction of an orthotopic neobladder using intestinal segments exist, but three basic principles must be satisfied for a successful outcome.

First, the patient must have an adequate external sphincter mechanism and nonobstructed urethra. This aspect is discussed in more detail later in the sections on patient selection and description of the anatomy of the external sphincter and surgical techniques for continence preservation.

Second, the reservoir must be sufficiently compliant to maintain a low pressure throughout the filling phase. This is best achieved by opening the bowel segment longitudinally to completely detubularize it and folding it to create a spheric shape. This concept was described by Goodwin and colleagues and further developed by Kock in elegant animal experiments (Goodwin et al, 1959; Eckman et al, 1964). The sphere has the greatest internal volume for a given surface area and thus the greatest capacity according to Laplace's law. The compliance of the wall relates to the physical characteristics of the bowel wall itself and is greater in small bowel compared with large bowel. The double-folded technique of Kock and S- and W-shaped reservoirs all effectively eliminate the coordinated high-pressure contractions of the bowel wall, allowing the reservoir to maintain low internal pressure throughout the filling phase (Kock et al, 1982; Hinman, 1988). All current continent diversion techniques use detubularized bowel to construct the reservoir.

Third, the reservoir must have adequate volume to allow for reasonable voiding intervals. In general, this should be at least 300 to 500 mL once the pouch is mature. All bowel segments effectively stretch over time if there is adequate outflow resistance. The standard 44-cm length of ileum formed into a double-folding reservoir by the Kock technique (also used for both the Studer and T pouch neobladders) has an initial capacity of less than 200 mL but within the first year stretches to hold 500 to 600 mL at low pressure (Studer et al, 1996). Figure 99-2 shows a computed tomography (CT) scan of a mature spheric pouch at 1 year. When used for a continent cutaneous pouch with high outflow resistance, this same configuration routinely stretches over time to hold more than 1000 mL at low pressure. This emphasizes that large initial volumes are not necessary to ultimately achieve an adequate voiding volume. Colonic segments do not stretch up as easily, and a larger initial volume is necessary for pouches constructed out of colon. In

Figure 99-2. Computed tomography scan of the pelvis after construction of an ileal neobladder (Studer pouch) showing the spheric shape achieved by 1 year.

general, small bowel, when available, has advantages over colon in terms of wall compliance and ability to stretch, as well as reduced mucous formation (Khafagy et al, 2006).

KEY POINTS: THREE BASIC PRINCIPLES OF ORTHOTOPIC NEOBLADDER CONSTRUCTION

- Patient must have a healthy urethra and adequate external sphincter function to maintain continence.
- Bowel segment should be detubularized and reconstructed into a spheric shape.
- Ultimate storage volume should be at least 300 to 500 mL at low pressure.

PATIENT SELECTION

Nearly all patients who undergo radical cystectomy may be considered at least potential candidates for orthotopic urinary diversion. There are few absolute contraindications. However, a number of factors should be considered in counseling the individual patient as to the best diversion for him or her, and these can be divided into cancer-related factors and patient factors.

Oncologic Factors

Risk of Urethral Recurrence in Men

The primary oncologic contraindication for orthotopic diversion is the presence of urothelial carcinoma at the urethral margin on intraoperative frozen section at the time of cystectomy. In the male patient involvement of the prostatic urethra is associated with a higher risk of subsequent urethral recurrence. Ashworth first reported on 7 patients with urethral recurrence, and noted that 5 of them had prostatic urethral involvement on the cystectomy specimen (Ashworth, 1956). Other series have subsequently confirmed this finding (Raz et al, 1978; Faysal, 1980; Hardeman and Soloway, 1990; Levinson et al, 1990; Tobisu et al, 1991; Nieder et al, 2004). Freeman and colleagues reviewed six studies in which 31 of 122 patients (25%) with evidence of prostatic urethral involvement developed an anterior urethral tumor after radical cystectomy for bladder cancer (Freeman et al, 1996). In a large, comprehensive, pooled analysis of 25 series, Stenzl and colleagues reported a total of 256 anterior urethral tumor recurrences in 3165 patients (8.1%) undergoing cystectomy for bladder cancer (Stenzl et al, 1995b).

A retrospective review of 768 men who underwent cystectomy without urethrectomy at the University of Southern California with 13 years' median follow-up found that the overall risk of urethral recurrence was approximately 7% at 5 years and 9% at 10 years. Recurrences were observed at a median of 2 years after cystectomy (range 0.2 to 13 years). The risk was only 5% at 5 years in the 639 patients without any prostate tumor involvement compared with 11% in the 129 men with any prostate involvement (Stein et al, 2005). The extent of prostatic tumor involvement correlated with the risk of subsequent urethral recurrence. The 5-year estimated probability of urethral recurrence for superficial carcinoma in situ (CIS) or mucosa and ductal prostatic urethral involvement without stromal invasion was 12%, compared with 18% with invasion into the stroma. In a multivariate analysis, any prostate tumor involvement (superficial or invasive) remained an independent and significant predictor of a urethral tumor recurrence. CIS in the bladder and tumor multifocality were not individually associated with a significant risk for anterior urethral recurrence (Stein et al, 2005).

Isolated prostatic stromal involvement is fairly unusual in the absence of nodal disease. In an updated study of 1226 male patients from the same institution, Djaladat and colleagues (2013) found only 33 patients who had prostatic stromal invasion without nodal involvement on final pathology. The urethral recurrence rate was

6% in this group, with a median time to recurrence of 2.4 years. None of these patients had a local pelvic recurrence (Djaladat et al, 2013).

A number of authors have evaluated other tumor characteristics to determine if histopathologic parameters other than prostatic urethral involvement can identify patients at increased risk for urethral recurrence after cystectomy. Various pathologic risk factors have been examined including the presence of papillary tumors, tumor multifocality, trigone or bladder neck tumor involvement, and associated CIS in the bladder or upper tracts (Freeman et al, 1996). Several investigators have evaluated the presence of CIS in the bladder as a risk factor for urethral recurrence with variable results (Hardeman and Soloway, 1990; Levinson et al, 1990; Tobisu et al, 1991; Stein et al, 2005). Boorjian and colleagues reviewed over 1500 patients (1230 males) with 13.5 years' median follow-up. They found that tumor multifocality was a significant risk factor for urethral recurrence in addition to prostatic urethral involvement but not CIS (Boorjian et al, 2011).

Some evidence indicates that orthotopic diversion itself may provide some protection against urethral recurrence. Stein reported on 397 patients who underwent neobladder diversion compared with 371 who did not. Median follow-up of both groups was long—10 years and 19 years—and patients were excluded if they underwent prophylactic urethrectomy. In patients without prostatic involvement (85% of the neobladder patients vs. 81% of the cutaneous diversion patients), the risk of urethral recurrence at 5 years was 3% versus 8%, respectively. In patients with prostatic stromal invasion, the 5-year risk of recurrence was 11% versus 24% for those with cutaneous diversion (Stein et al, 2005). Boorjian found a similar protective effect of neobladder reconstruction in the Mayo Clinic series of over 1200 male patients with long follow-up. Both these studies found this effect persisted when other pathologic variables were controlled for (Boorjian et al, 2011). The reason for this observation is unclear, although there has been speculation that continued flow of urine, perhaps with changes in urinary characteristics caused by the interposed bowel, might be responsible (Stein et al, 2005).

There is some controversy about the importance of attempting to identify prostatic urethral involvement preoperatively, as well as what to recommend for those patients in whom prostatic involvement is identified. At the time of transurethral resection (TUR) of the primary bladder tumor, the surgeon may perform deep TUR biopsies of the prostate, preferably at the 5- and 7-o'clock positions lateral to the verumontanum. This should certainly be done if the mucosa of the prostate looks suspicious. Some authors have recommended that this should be done routinely and have advocated repeat TUR before cystectomy in patients in whom it was omitted (Wood et al, 1989; Sakamoto et al, 1993; Lerner and Shen, 2008). However, the reliability of preoperative transurethral prostatic biopsies has been challenged by others. In a prospective series of 118 patients, Lebret and colleagues examined the usefulness of preoperative prostatic biopsies compared with intraoperative frozen-section analysis of the prostatic urethral margin at the time of cystectomy in predicting urethral recurrence. They found that intraoperative frozen-section analysis was more accurate than any preoperative parameter including preoperative prostate biopsies in predicting urethral recurrence (Lebret et al, 1998). In another series of 246 men who underwent preoperative transurethral loop biopsy of the prostate, Donat and colleagues reported that this preoperative pathologic evaluation did not accurately determine prostatic tumor involvement—both false-negative and false-positive results were observed. Forty-three percent of patients with prostatic involvement on final pathology were missed on the TUR biopsy, and 12 of 36 patients with prostatic stromal invasion identified on TUR specimen had no residual prostatic involvement on the final cystectomy specimen (Donat et al, 2001). In light of this, it is questionable whether the risk of the additional anesthetic and the potential delay to definitive surgery warrant the additional information garnered by a repeat TUR with prostatic urethral biopsy. We have not routinely recommended repeat TUR solely to rule out prostatic involvement before cystectomy. Other centers have adopted a similar

philosophy with comparable clinical outcomes (Iselin et al, 1997; Hautmann, 2003).

It has been our practice to counsel patients with documented prostatic mucosal, ductal, or stromal invasion about the increased risk of urethral recurrence if the urethra is left in situ, and to help them weigh that risk against any perceived advantage of an orthotopic diversion. In general, those with prostatic stromal invasion are counseled to undergo neoadjuvant chemotherapy. In those who are not candidates for neoadjuvant chemotherapy or who have persistent prostatic urethral involvement, at surgery a concomitant urethrectomy and cutaneous form of diversion are recommended. Close surveillance of the urethra is mandatory if a neobladder procedure is performed, with periodic urethral wash cytology and urethroscopy as indicated.

Risk of Urethral Recurrence in Women

In the past, urethrectomy was routinely performed at the time of radical cystectomy in women. With the acceptance of continent neobladder in men, a number of investigators began evaluating the feasibility of preservation of the urethra in women. This was initially attempted in women with non-transitional cell carcinoma in whom there was little concern about possible urethral recurrence, with excellent functional results (Stein et al, 1994b). Before this it was generally believed that the bladder neck was the primary continence mechanism in women, but initial clinical experience proved that one could achieve excellent continence by dividing the urethra distal to the bladder neck (Tanagho et al, 1966; Stein et al, 1994b).

Two important pathologic studies were critical to the ultimate decision to expand urethral-preserving cystectomy to women with urothelial carcinoma. Stein and colleagues retrospectively evaluated a series of archival cystectomy specimens from 67 female patients undergoing cystectomy with urethrectomy for bladder cancer with re-evaluation of the primary pathology specimen. Seventeen of these women (25%) had involvement of the bladder neck, and 9 (13%) of them had urethral involvement. All female patients with an uninvolved bladder neck also had an uninvolved urethra (no skip lesions), whereas approximately 50% of patients with a bladder neck tumor had concomitant urethral tumor involvement. Risk factors for urethral involvement in this study included increased grade, stage, and lymph node involvement, but the presence of CIS did not predict urethral involvement. Vaginal wall involvement was also a major risk factor for urethral involvement. Although vaginal wall invasion was a relatively rare event (1%), all of these patients also had bladder neck involvement and 50% had urethral extension (Stein et al, 1995). The presence of vaginal wall invasion is best evaluated with bimanual examination under anesthesia, either at TUR or cystectomy.

Stenzl and colleagues also studied the risk of synchronous or secondary urethral tumors with long-term follow-up in 356 women with bladder cancer of all stages. They found urethral involvement in only 2% of the patients, and it was always associated with bladder neck involvement. Of the patients with cT2 to T4 localized disease, only 1% had urethral involvement.

No correlation between urethral tumors and other pathologic factors such as CIS or tumor multifocality was found. The researchers concluded that the urethra can be safely preserved in selected female cystectomy patients provided that neither preoperative biopsy specimens of the bladder neck nor intraoperative frozen-section specimens of the proximal urethra demonstrate any tumor or atypia (Stenzl et al, 1995b).

Maralani and colleagues similarly evaluated specimens from 43 female patients who underwent cystectomy for bladder cancer. They reported a 16% incidence of urethral tumor involvement, and vaginal involvement in this study was the most significant risk factor for urethral tumor involvement (Maralani et al, 1997). Chen and colleagues also retrospectively reviewed the risk of urethral, vaginal, and cervical involvement by transitional cell carcinoma in 115 women undergoing radical cystectomy. They found an overall 8%

incidence of tumor of the urethra, and confirmed an association between urethral tumor and tumor at the bladder neck or invading the vagina or cervix. They did find 2 patients with urethral tumor who did not have bladder neck involvement, though the researchers did not do pathologic review of the specimens. These studies and others confirmed that the most significant risk factor for urethral tumor involvement is tumor at the bladder neck (De Paepe et al, 1990; Coloby et al, 1994; Chen et al, 1997).

Stein and colleagues (1998a) embarked on a prospective study to evaluate and confirm the previously established pathologic risk factors in women undergoing cystectomy for bladder cancer to determine if these criteria safely identify appropriate female candidates for orthotopic diversion. Final pathologic analysis of the bladder neck and proximal urethra was performed and compared with the intraoperative frozen-section analysis of the proximal urethral margin. Tumor involvement at the bladder neck and proximal urethra was found in 14 (19%) and 5 (7%) cystectomy specimens, respectively. All patients with urethral tumors also demonstrated concomitant bladder neck tumors. Bladder neck tumor involvement was again found to be the most significant risk factor for tumor involving the urethra, confirming the findings from retrospective series. However, approximately half of patients with bladder neck tumors had a normal (tumor-free) proximal urethra. Furthermore, no patient with a normal bladder neck demonstrated tumor involvement of the urethra. In all cases, intraoperative frozen-section analysis of the proximal urethra correlated with and was correctly confirmed by final permanent section (Stein et al, 1998a). These results suggest that one may depend on the intraoperative frozen section to determine the feasibility of orthotopic diversion. Stenzl and colleagues reported similar results (Stenzl et al, 1998).

Clinical follow-up data from the first 88 women who underwent orthotopic diversion at University of Southern California showed that no urethral recurrences were observed with a median follow-up of 30 months in this group (Stein et al, 2002). Ali-El-Dein and colleagues (2004) prospectively evaluated 145 women undergoing cystectomy and orthotopic diversion. Two patients developed urethral recurrence. One had a primary squamous cell cancer of the bladder, and the other had urothelial carcinoma with CIS of the trigone (Ali-El-Dein et al, 2004). This series was updated with 180 patients and median follow-up of 57 months, with still only 2 documented urethral recurrences. There were no isolated vaginal wall recurrences. In this series the researchers found uterine or cervical involvement in only 1% of patients, which was suspected preoperatively in all patients based on imaging (Ali-El-Dein, 2009).

Locally Advanced Tumor Stage

Many urologists are hesitant to perform continent orthotopic diversion in patients with locally extensive disease. This is based on two factors: (1) concern about the possible impact of local recurrence on the neobladder itself and (2) a belief that these patients are doomed to suffer distant recurrence and have a shortened life expectancy and will not benefit from the neobladder.

Radical cystectomy with bilateral pelvic or iliac lymphadenectomy provides excellent local (pelvic) control for the treatment of invasive bladder cancer. Stein and colleagues reported the clinical outcomes for 1054 patients who underwent radical cystectomy for bladder cancer with a median follow-up of more than 10 years. In this series, an overall local pelvic recurrence rate of 7% was observed for the entire group of patients. The risk of pelvic recurrence ranged from 6% with organ-confined, node-negative disease to 13% for patients with extravesical or node-positive disease. Nearly 50% of patients with extravesical tumor extension and 30% of patients with lymph node positive disease were still alive without evidence of disease 5 years after cystectomy. These results suggest that local recurrence even for patients demonstrating locally advanced or lymph node positive disease is relatively infrequent and that a significant proportion of these patients will be long-term survivors and may benefit from continent diversion (Stein et al, 2001a). In an update review of 1817 patients from the same institution and a

median follow-up of 11.7 years, only 81 (4.5%) of patients had pelvic recurrence without distant metastases (Mitra et al, unpublished data).

If local tumor recurrence does develop in patients with an orthotopic diversion, only a minority will develop problems related to the urinary diversion itself. Hautmann and colleagues evaluated this issue in 43 of 357 men who underwent radical cystectomy and ileal neobladder and developed local recurrence. Most of them (84%) had advanced disease (stage pT3a or higher) on final pathology at the time of cystectomy. A total of 17 patients (43%) had concomitant distant metastasis at the time of diagnosis of the local recurrence. Local recurrence interfered with the upper urinary tract in 24 patients, the neobladder in 10 (23%), and the intestinal tract in 7; only 1 patient required removal of the neobladder because of an intestinal fistula. The authors concluded that **most patients could anticipate normal neobladder function even in the presence of locally recurrent disease** (Hautmann and Simon, 1999). Similarly, Tefilli and colleagues found that 1 of 11 patients with orthotopic diversion and local recurrence required conversion to an ileal conduit because of invasion of the neobladder (Tefilli et al, 1999).

Questions were initially raised about whether a planned neobladder reconstruction would result in the surgeon inadvertently compromising the extent of dissection and thus the cancer cure rate. To evaluate this, Yossepowitch and colleagues retrospectively evaluated 214 patients who underwent radical cystectomy and orthotopic reconstruction and compared them with 269 patients treated with a cystectomy and ileal conduit diversion. Adjusting for pathologic stage, there was no cancer-specific survival difference between the two diversion groups. Patterns of relapse in 62 of the 214 patients (29%) with an orthotopic neobladder included local recurrence in 11%, distant recurrence in 9%, and combined local and distant recurrence in 18%. Only one patient in this series required the neobladder to be converted to an ileal conduit secondary to a relapse at the ureteroenteric anastomosis and expanding into the pouch. These authors also concluded that **the low risk of local recurrence showed that in this cohort of patients the oncologic efficacy of the operation was not compromised** (Yossepowitch et al, 2003).

KEY POINTS: ONCOLOGIC FACTORS IN PATIENT SELECTION

- The presence of CIS, multifocal tumor, or extravesical disease should not preclude orthotopic diversion if frozen section of the urethral margin is negative at surgery.
- The most significant risk factor for a urethral tumor recurrence in men after orthotopic diversion is the presence of prostatic stromal invasion on final pathology.
- The most important risk factor in women for urethral tumor involvement is bladder neck or anterior vaginal wall involvement with cancer. The latter is best evaluated on bimanual examination under anesthesia at the time of transurethral resection of the bladder tumor or cystectomy.
- Intraoperative frozen-section analysis of the urethral margin in men and women provides an accurate assessment of the urethra and appropriately determines candidacy for orthotopic diversion. Preoperative biopsy of the prostatic urethra or bladder neck is not mandatory.
- Local pelvic recurrence should occur in less than 10% of patients undergoing an appropriate cystectomy and pelvic lymphadenectomy for bladder cancer and rarely interferes with the function of the neobladder. The risk of recurrence is not increased by careful preservation of the urethra during the cystectomy.

Patient-Related Factors

A number of patient-related factors need to be considered when advising a patient about the best form of urinary diversion. These

include the patient's general health and social circumstances, baseline renal function, presence of a healthy urethra and functioning sphincter muscle, manual dexterity, and previous treatments including pelvic radiation, prostate surgery, or bowel resection. Perhaps equally important is the patient's personal preference and attitudes about the risk of incontinence, potential need to self-catheterize, and management of an external appliance. The relative importance of each of these factors in determining how to counsel an individual patient must be decided on a case-by-case basis. The patient and his or her family must have a realistic understanding of the pros and cons of each type of diversion before making a decision. There is a natural inclination for most patients to opt for an orthotopic reconstruction because it is the most "natural." They must gain the understanding that problems can occur with each type of diversion, although the specific types of problems differ. An honest, informed discussion should take place, with the physician carefully explaining the various options along with the short- and long-term risks and benefits of each form of urinary diversion. It may also be helpful to have the patient talk with other patients who have undergone the various forms of urinary reconstruction. In general, patients with poor general health, the frail elderly, and patients with high surgical risks, difficult social circumstances, or poor cognitive function are probably best managed with an ileal conduit.

Age

Many authors have evaluated the success of continent diversion in elderly patients (Lance et al, 2001; Clark et al, 2005; Sogni et al, 2008). Although elderly patients undergoing orthotopic diversion may take longer to regain continence and have a higher rate of mild stress incontinence, ultimately older patients achieve daytime and nighttime continence rates similar to those for younger patients (Elmajian et al, 1996; Steven and Poulsen, 2000). **The clear consensus is that chronologic age alone is not a contraindication for continent diversion and that options should be considered for each patient on the basis of other factors** (Hautmann et al, 2013). Medical comorbidities; renal, cardiac, pulmonary, and cognitive function; and manual dexterity are all important factors that should be considered in the elderly, along with the patient's social support situation. A conduit may be easier for a caregiver to manage than an orthotopic diversion with the risk of incontinence and possible need for catheterization. However, an active, generally healthy, independent elderly patient may certainly be considered a reasonable candidate for orthotopic diversion depending on his or her wishes.

Renal Function

One of the most important contraindications for continent neobladder reconstruction is compromised renal function. Urinary electrolytes including urea, potassium, and chloride are reabsorbed from the small bowel mucosa with excretion of sodium and bicarbonate, resulting in an increased acid load that must be processed by the kidneys. In patients with compromised renal function, hyperchloremic metabolic acidosis can develop along with worsening dehydration, uremia, nausea, and bone loss. The exact level of acceptable renal function for consideration for continent diversion is somewhat controversial. In one study looking at short-term change in renal function in 168 patients (124 continent diversion vs. 44 ileal conduit), the mean decrease in estimated glomerular filtration rate (eGFR) from before to after surgery in the two groups was 4.1 mL/min and 10.3 mL/min, respectively, at a median follow-up of 18.7 months. There was no significant difference in this drop between those with eGFR of 60 mL/min or higher and those whose eGFR was between 40 and 59 (Winters et al, 2013). On the other hand, in a prospective study of 484 patients undergoing two types of neobladder procedures, preoperative lower eGFR was highly correlated with the risk of subsequent decline in eGFR of more than 10 mL/min by 3 years (Skinner et al, 2012). As a general rule, a serum creatinine level of less than 1.7 to 2.2 mg/

dL (150 to 200 $\mu\text{mol/L}$) or an estimated creatinine clearance (eGFR) of greater than 35 to 40 mL/min is recommended for patients considering continent diversion (Hautmann, 2003; Hautmann et al, 2013). However, decision making in individual patients can at times be less clear-cut. Acute upper tract obstruction caused by the tumor often results in a transient rise in creatinine, which would be expected to improve after cystectomy and should be taken into account when counseling patients. There is no evidence that orthotopic diversion leads to progressive renal dysfunction in patients with normal renal function before surgery.

Body Habitus

Obesity is not a contraindication for orthotopic diversion, although placing the urethral sutures and working with the thick bowel mesentery may be challenging. **In fact, an obese patient may be better served with orthotopic diversion because of the difficulty constructing a functional conduit stoma with a very thick abdominal wall.**

Manual Dexterity and Willingness to Do Self-Catheterization

The need to do occasional or routine self-catheterization is reported in 10% to 50% of men and in up to 30% to 60% of women (see later). In general, it is impossible to predict which patients will require catheterization to empty, and retention can occur many years after the initial surgery. **Thus all patients considered for continent diversion should be willing and able to do self-catheterization.** We try to have each patient meet with a nurse or enterostomal therapist before surgery to go over this technique. This is particularly important in women, in whom the potential need to do self-catheterization is higher and sometimes technically more difficult than in men. Although most patients are hesitant about this potential requirement, it is rare for a patient to decide against an orthotopic diversion because of this once he or she has been educated about it.

Urethral Stricture Disease or External Sphincter Damage

Severe urethral stricture disease in men and women is a **contraindication for orthotopic diversion.** Poor external sphincter function in a man who is highly motivated to undergo orthotopic diversion may be managed with a concomitant or delayed artificial urinary sphincter device (Simma-Chiang et al, 2012). Similarly, a woman with significant stress incontinence might undergo a concomitant Burch or pubourethral sling procedure, although she would most likely be dependent on intermittent catheterization to drain properly if that were done.

Prior Pelvic Radiation

It is not uncommon for patients to require surgical management of invasive bladder cancer after previous failed radiation therapy or after radiation treatment of a prior pelvic malignancy. In the series from University of Southern California, 8.5% of 1471 patients had some prior pelvic radiation. This exposure can significantly increase the difficulty of the surgery and can affect wound healing and postoperative complications. Many surgeons are hesitant to offer orthotopic diversion in this setting.

Patients with prior radiation are at increased risk of several complications, even with an ileal conduit diversion. Kim and Steinberg (2001) found an increased risk of surgical complications, especially those that required percutaneous or surgical intervention, in 23 patients undergoing cystectomy and conduit after radiation compared with 23 matched controls. Chang and colleagues (2004) evaluated outcomes of ileal conduits in 36 patients with prior radiation. They found that ureteroileal complications occurred in 9% of patients by 5 years and concluded that it was appropriate to use ileum for diversion rather than a colon conduit (Chang et al, 2004).

The complications and ultimate functional outcome of orthotopic neobladders in patients with prior pelvic radiation have been

evaluated by a number of authors. Bochner and colleagues described their early experience with salvage surgery and orthotopic bladder substitution after failed radical radiation therapy. A total of 18 patients who had prior radiation therapy (minimum dose, 60 Gy) for bladder or prostate cancer were evaluated. Operative characteristics, postoperative outcomes, and complications (related or unrelated to the urinary diversion) were found to be similar in irradiated and nonirradiated patients (Bochner et al, 1998). This series was recently updated by Eisenberg and colleagues with a total of 48 patients undergoing neobladder reconstruction (32.4% of all patients with the same level of irradiation who underwent salvage cystectomy). Age and higher American Society of Anesthesiologists (ASA) score were associated with more early complications, but not the type of urinary diversion. However, these were clearly a highly selected group of patients who had the least visible damage to the external sphincter and were thought likely to have a good outcome. In spite of this, urinary incontinence was more common than in the larger series of nonirradiated patients (Eisenberg et al, 2010).

Nieuwenhuijzen and colleagues reported on 27 patients who underwent salvage cystectomy, 9 of whom had an orthotopic diversion. Eight of them achieved complete daytime continence, similar to results expected in nonirradiated patients (Nieuwenhuijzen et al, 2004). Hautmann also reported on 25 patients (18 males and 7 females) who underwent neobladder construction after high-dose irradiation. This constituted 2.5% of the entire group of neobladder patients and a quarter of those who underwent salvage cystectomy at that institution. Early and late outcomes were similar to those in the larger group of nonirradiated patients. Hautmann concluded that indications to be considered for a neobladder in irradiated patients include absence of preoperative incontinence or stricture, no fistula formation, and no severe bowel radiation damage (Hautmann et al, 2009).

It is clear that in carefully selected patients, orthotopic lower urinary tract reconstruction can be performed after definitive, full-dose pelvic irradiation. Even selected women with a history of pelvic irradiation may be appropriate candidates for orthotopic reconstruction with good clinical outcomes (Stein et al, 2002; Lee et al, 2004). However, these are challenging procedures that clearly require technical expertise and keen intraoperative judgment. Previous high-dose prostate radiation (external beam or brachytherapy) or a vaginal implant for cervical cancer cause more scarring in the rhabdosphincter area than does external beam radiation for either bladder cancer or other malignancies. Interstitial seed implants for prostate cancer often end up in the levator muscles and urogenital diaphragm and may result in severe scarring around the area of the external sphincter.

Preoperative evaluation including cystoscopy is mandatory to evaluate the integrity of the mucosa around the area of the sphincter. However, it may not be possible to accurately predict the degree of radiation damage found at surgery, so **careful intraoperative tissue assessment and determination of the condition of the urethra, ureters, and bowel must be performed to make a final decision about the feasibility of orthotopic diversion** (Abbas et al, 2001). These patients should always be counseled preoperatively that the orthotopic diversion may not be possible.

Prior Prostate Surgery or Bowel Resection

Prior abdominal or pelvic surgery may also present challenges for the surgeon performing orthotopic diversion. **Patients who have had a prior radical prostatectomy may have a particularly difficult dissection around the proximal urethra at the prior vesicourethral anastomosis.** Nevertheless, this is often feasible with careful dissection. The location and health of the proximal urethra can be assessed endoscopically both preoperatively and at surgery, and acceptable continence can be obtained in selected patients assuming that they had good continence before cystectomy (Schuster et al, 2003; Huang et al, 2012). Huang and colleagues reported on 24 patients who underwent ileal neobladder construction after cystectomy following prior radical prostatectomy (20) or prostatectomy plus adjuvant radiation (4). Nine patients had fair

or poor continence before surgery, and 6 of those underwent artificial sphincter placement either at the time of cystectomy or after. However, 11 of the 13 men with good preoperative continence, including 1 who had prior radical prostatectomy and radiation, regained good continence (0 or 1 pad per day) after neobladder construction. There were no rectal injuries and no anastomotic strictures in this series (Huang et al, 2012).

One challenge in these surgeries is to identify the prior vesico-urethral anastomosis to ensure that the bladder is entirely resected. Flexible cystoscopy at the time of the apical dissection can assist in this regard. In conclusion, with careful dissection a patient who was continent after the initial radical prostatectomy surgery can be expected to have an acceptable result with a neobladder.

A patient with multiple prior bowel resections may be at risk of developing chronic diarrhea or even short bowel syndrome after an additional 45 to 60 cm of small bowel is resected. In these patients, alternatives to orthotopic diversion such as a sigmoid neobladder might be entertained. In general, prior bowel resections can be managed by carefully dissecting out all of the small bowel, taking down any adhesions before performing the diversion. **It is critical to identify the old bowel anastomosis and, whenever possible, take that down and use that site as one end of the continent reservoir.** This avoids potential devascularization of the bowel segment between the old and new bowel anastomoses.

KEY POINTS: PATIENT-RELATED FACTORS

- Adequate renal function (eGFR exceeding 35 or 40 mL/min) is recommended for patients considering continent diversion.
- Older age and obesity are not contraindications to orthotopic diversion.
- Orthotopic lower urinary tract reconstruction can be performed after definitive, full-dose pelvic irradiation and after prior radical prostatectomy in carefully selected male and female patients.
- In patients with prior bowel resection the prior anastomosis should be taken down and that segment used for the orthotopic diversion rather than choosing a new site, to avoid devascularization of the bowel.

CONTINENCE MECHANISM IN PATIENTS UNDERGOING ORTHOTOPIC DIVERSION

An understanding of the anatomy of the urethral continence mechanism in men and women is crucial to preserving this function at the time of radical cystectomy. The surgical dissection at the prostatic apex in men and bladder neck in women must be carefully and precisely performed to achieve optimum continence while taking care not to compromise the oncologic effectiveness of the surgery.

Much of what has been learned of the rhabdosphincter complex comes from elegant neuroanatomic studies of the female urethra. Colleselli and colleagues performed extensive microneuroanatomic dissections, histologic examination, and three-dimensional reconstructive imaging to better define the urethral sphincteric and rhabdosphincteric anatomy in women. The female urethral sphincter system consists of smooth muscle innervated by the autonomic nervous system and striated muscle supplied by somatic nerves. There is general agreement that the autonomic nerves that serve the smooth muscle sphincter originate in the pelvic plexus. These autonomic fibers emerge from the pelvic plexus and course along the lateral aspect of the rectum and vagina toward the bladder neck and very proximal urethra. Some of these fibers branch off from a thick fiber at the lower margin of the lateral vaginal wall and enter the bladder neck and cranial portion of the urethra from the dorsolateral aspect. These autonomic nerves do not appear to play a significant role in the innervation of the rhabdosphincter

or the continence mechanism and are essentially sacrificed during the exenterative portion of the operation without compromising continence (Colleselli et al, 1998).

Innervation of the voluntary urinary sphincter system, however, is a matter of some controversy. **Most investigators agree that the rhabdosphincter is supplied primarily by the branches of the pudendal nerve** (Borirakchanyavat et al, 1997; Stenzl et al, 1997; Colleselli et al, 1998). Although these dissections were performed on female cadavers, the observations and findings have been similarly described in men (Strasser and Bartsch, 2000). Collectively, these findings have allowed a more precise and anatomic approach to maintain the continence mechanism in all patients undergoing cystectomy and orthotopic substitution.

In the same study, Colleselli and colleagues found that the major portion of the striated muscle that corresponds to the striated rhabdosphincter is located on the ventral and lateral aspects (omega shaped) of the urethra. No clearly defined line could be identified between the transverse smooth muscle cranially and the striated muscle caudally. Rather, a gradual transition was noted in the middle third of the urethra, with intermingling fibers of both types of muscle (Colleselli et al, 1998). This area has been found to correspond to the area of continence region on fluorourodynamic studies performed on women who had undergone orthotopic reconstruction after cystectomy (Grossfeld et al, 1996). Branches off the pudendal nerve coursing beneath the levator muscle can be traced to the rhabdosphincter. Delicate fibers from the perineal portion of the pudendal nerve course underneath the urogenital diaphragm, entering the caudal portion of the urethra laterally (Colleselli et al, 1998; Hinata et al, 2012).

In a neuroanatomic study performed in male human cadaveric pelvis, similar anatomic findings and innervation were described. Strasser and Bartsch described the male rhabdosphincter as an independent muscle unit that is not in direct contact with the fibers of the levator ani muscle. These dissections demonstrated that the male sphincter does not form a horizontal muscular ring around the membranous urethra. Rather, the male rhabdosphincter is a muscular coat situated ventral and lateral to the membranous urethra and prostate, the core of which is an omega-shaped loop that surrounds the membranous urethra. The innervation of the male rhabdosphincter was also found to originate from fine branches that arise off the pudendal nerve. These authors suggested that injury to either the rhabdosphincter or the pudendal innervation may impair the sphincter mechanism in men (Strasser and Bartsch, 2000).

SURGICAL TECHNIQUES FOR CONTINENCE PRESERVATION DURING RADICAL CYSTECTOMY

Anterior Apical Dissection in the Male Patient

The technique of radical prostatectomy with an extended bilateral pelvic lymphadenectomy is well established (Stein and Skinner, 2004). Attention to anatomic and surgical detail is important to optimize functional and clinical outcomes in patients undergoing orthotopic diversion. Minimal manipulation of the muscle fibers of the rhabdosphincter, fascial attachments, and corresponding innervation is essential to providing optimal urinary continence (Colleselli et al, 1998; Stenzl et al, 1998; Strasser and Bartsch, 2000; Stein et al, 2001b). Several fundamental key surgical issues in the preparation of the urethra in patients undergoing orthotopic diversion deserve special mention.

In a standard cystectomy the bladder and prostate are completely freed off the rectum and mobilized posteriorly before the urethral dissection. Posterior dissection should not extend distal to the apex of the prostate. If a nerve-sparing approach is planned, the urethra may be divided after the lateral pedicles are taken down to the bladder (anterior branches of the internal iliac vessels) before the posterior dissection is performed. The prostate is then dissected in a retrograde fashion off the rectum and bilateral neurovascular bundles, and the posterior pedicles are divided last.

In either approach, all fibroareolar connections along the anterior bladder wall, prostate, and undersurface of the pubic symphysis are divided. The endopelvic fascia is incised adjacent to the prostate, and the levator muscles are gently swept off the lateral and apical portions of the prostate. The superficial branch of the deep dorsal vein is identified, ligated, and divided. With tension placed posteriorly on the prostate, the puboprostatic ligaments are identified and slightly divided just beneath the pubis and lateral to the deep dorsal venous complex (DVC), which courses between these ligaments. Care should be taken to avoid any extensive dissection in this region. The puboprostatic ligaments need to be incised only enough to allow proper apical dissection of the prostate.

Several methods can be performed to properly control the DVC as discussed in Chapters 114 and 115. We use absorbable suture to avoid the risk of erosion of suture, clips, or staples into the urethral anastomosis. Once the venous complex has been ligated, it may be divided close to the apex of the prostate. Any bleeding from the transected venous complex can be controlled with an absorbable suture. **Care should be taken to avoid deep suture bites into the complex or levator muscles, which could injure the continence mechanism.** The DVC suture can then be used to suspend the venous complex anteriorly to the periosteum of the symphysis pubis to re-establish anterior fixation of the DVC and puboprostatic ligaments, which may enhance continence recovery (Bauer et al, 2011).

The anterior urethra is then incised just beyond the apex of the prostate. Six 2-0 absorbable monofilament or woven polyglycolic acid sutures are placed in the urethra circumferentially under direct vision, carefully incorporating only the wall of the urethra without incorporating the levator muscles. Placing the urethral sutures at this time rather than after the bladder has been removed avoids the retraction of the urethra that makes subsequent accurate placement difficult. The urethral catheter is clamped and divided distally. Two additional sutures are then placed, incorporating the rectourethralis muscle posteriorly and the caudal extent of the Denonvilliers fascia. After this, the posterior urethra is divided and the specimen removed. The urethral sutures are tagged to identify their location and are placed under a towel until the urethroenteric anastomosis is performed.

Frozen-section analysis of the circumferential distal urethral mucosal margin (prostatic apex) on the cystectomy specimen is performed to exclude tumor involvement. If there is no evidence of tumor, orthotopic reconstruction may be performed. If there is tumor at the prostatic apex, the urethral stump can be excised or a total urethrectomy may be performed at this time to obtain a negative margin, and a cutaneous diversion constructed.

Preservation of the Urethra in the Female Patient

When orthotopic diversion is considered in female patients, several technical issues should be noted to optimize the continence mechanism (Stein et al, 2001b; Stein and Skinner, 2004). A standard female cystectomy includes removal of the uterus, cervix, and ovaries (anterior exenteration). However, in selected females with clinically lower-stage disease, a number of authors have advocated preservation of the uterus and ovaries (Chang et al, 2002; Zippe et al, 2005; Djaladat et al, 2012; Ali-El-Dein et al, 2013). It appears that preserving the uterus and its supportive ligaments eliminates the risk of vaginal fistula, improves sexual function, and may decrease urinary retention in women undergoing neobladder reconstruction (see later). Whether the uterus is removed or not, **when-ever possible the bladder is dissected completely off the anterior vaginal wall rather than excising it.** However, a deeply invasive tumor on the posterior bladder or trigone may necessitate excision of a portion of the anterior vaginal wall. This does increase the risk of subsequent pouch-vagina fistula but is not an absolute contraindication to orthotopic reconstruction. A patient with a significant tumor at the bladder neck or with palpable extension into the vaginal wall is a poor candidate for neobladder and should undergo en bloc urethrectomy and cutaneous diversion.

In developing the posterior pedicles, if a hysterectomy is planned the posterior vagina is incised at the fornix behind the cervix. If the

patient has undergone prior hysterectomy, a sponge stick in the vagina facilitates identification of the vaginal apex. In that case the vagina is usually not entered. Before dissecting off the bladder, the posterior vascular pedicles coursing around the vagina to the bladder are developed and divided. The vaginal apex may be grasped with a clamp to provide countertraction, and scissors are used to dissect right along the lateral vaginal wall. This develops the posterior pedicle coming around the rectum and vagina toward the bladder, which can be controlled with hemoclips, vascular staples, or a LigaSure (Covidien, Mansfield, MA) or similar device. Care is taken to dissect along the midlateral vaginal border, rather than dissecting back along the rectum or anterior into the bladder.

The issue of nerve-sparing cystectomy in women is controversial. Some authors have suggested that preservation of the sympathetic nerves coursing along the lateral vaginal wall may contribute to maintaining continence in women undergoing orthotopic diversion (Stenzl et al, 1995a; Hautmann, 1997; Turner et al, 1997; Stenzl et al, 1998; Bhatta et al, 2007). Others have not made any special effort to preserve the autonomic nerves and have successfully relied on the pudendal innervation of the rhabdosphincter complex for continence (Stein et al, 1997, 2004; Ali-El-Dein et al, 2002; Ali-El-Dein, 2009). Thus it appears that preservation of the perivaginal nerves may not be absolutely required to maintain continence in women.

Once the posterior pedicles have been divided, careful dissection of the bladder off of the anterior vaginal wall is performed sharply. Care must be taken to dissect in the proper plane to prevent entry into the posterior bladder and reduce the amount of bleeding in this vessel-rich area. **It is absolutely critical not to compromise the oncologic success of the surgery by inadvertent dissection into the bladder.** Dissection is carried caudally to the vesicourethral junction. Tugging on the Foley catheter balloon to position it at the bladder neck assists in identifying this junction.

Once the posterior dissection is completed, the fatty tissue overlying the anterior urethra is swept off the endopelvic fascia and the vesicourethral junction is carefully identified. Again, tugging on the Foley catheter allows the surgeon to visualize the junction between the urethra and bladder. **The endopelvic fascia and periurethral tissue anteriorly should not be disturbed in this process. The proximal urethra in the female extends well above the endopelvic fascia (Fig. 99-3).** Careful sharp dissection is used to free the bladder neck and an initial 0.5 cm of urethra off the vagina. At this point the specimen is attached only by the urethra itself.

Figure 99-3. Preparation of the female urethra for an orthotopic neobladder. The fatty tissue overlying the anterior urethra is swept off the endopelvic fascia and the vesicourethral junction is carefully identified by positioning the Foley catheter at the bladder neck. Note that the endopelvic fascia and periurethral tissue anteriorly are not disturbed.

After the site for the incision is marked just distal to the vesicourethral junction, the Foley catheter can be removed and a pedicle clamp placed across the bladder neck, which prevents any tumor spill from the bladder when the urethra is transected. The proximal urethra is sharply divided just distal to the bladder neck. The female urethra does not retract away after division as it does in the male, so sutures can be placed after removal of the bladder. Frozen-section analysis is performed on the urethral margin of the cystectomy specimen to exclude any tumor. Once the decision is made to perform the orthotopic diversion, 8 to 10 individual 2-0 absorbable sutures are placed circumferentially through the urethra, tagged, and set aside.

In the case of a deeply invasive posterior bladder tumor, the anterior vaginal wall may be removed en bloc with the cystectomy specimen by incision along the long axis of the anterolateral vaginal wall. This leaves the anterior vaginal wall attached to the bladder specimen. Again, the Foley catheter balloon facilitates identification of the vesicourethral junction. A rim of anterior vaginal wall must be preserved proximal to the urethra to close the vagina so that the vaginal suture line is not directly abutting the vesicourethral suture line to decrease the risk of subsequent fistula. The vagina may be closed in a clamshell or horizontal manner. Other reconstructions to increase vaginal volume are feasible, but it may be difficult to perform a complex vaginal reconstruction (e.g., a rectus myocutaneous graft) along with a neobladder procedure simply because of a lack of adequate room in the pelvis.

The vagina is then closed at the apex with absorbable suture and then suspended. One may suspend the vagina to the Cooper ligament or to preserved cut ends of the round ligaments to prevent postoperative vaginal prolapse. However, we routinely perform a sacrocolpopexy incorporating a short strip of permanent mesh to fix the vagina to the sacral promontory at a more natural angle without any tension. This may be important to support the neobladder and avoid a possible cause of late voiding difficulty. Regardless of the form of vaginal reconstruction, a well-vascularized omental pedicle graft should be placed between the reconstructed vagina and the neobladder and secured to the endopelvic fascia at either side of the urethral stump to separate the suture lines and prevent fistula formation between the vaginal and urethral anastomosis, which may help support the pouch posteriorly.

KEY POINTS: CONTINENCE MECHANISM AND SURGICAL TECHNIQUES FOR CONTINENCE PRESERVATION

- The innervation of the striated urethral rhabdosphincter arises from the branches of the pudendal nerve and is most important to maintain continence in patients with an orthotopic neobladder.
- The striated rhabdosphincter muscle fibers are concentrated in the area anterior and lateral to the proximal urethra.
- In male patients, one should obtain careful control of the DVC and avoidance of deep suture bites into the pelvic floor muscles.
- In female patients, the endopelvic fascia and levator muscles should not be disturbed.

TECHNIQUES FOR ORTHOTOPIC BLADDER SUBSTITUTION

Choice of Bowel Segment

A number of different procedures for orthotopic reconstruction incorporating different segments of bowel have been described. There are clearly some physiologic indications to use various segments of intestine, but the surgeon's preference may be even more influential. It has been suggested that **excellent functional and clinical outcomes with voiding can be achieved regardless of the**

segment of bowel chosen as long as the principles of preservation of the rhabdosphincter as a continence mechanism and construction of an adequate capacity, low-pressure reservoir are maintained (Parekh et al, 2000b; Lee et al, 2003). Ideally, the surgeon performing orthotopic urinary diversion will be comfortable using a variety of the techniques described later so that he or she can adapt the technique to the needs of the individual patient.

Reservoirs made of detubularized ileum or ileum and colon together appear to have the greatest compliance and lowest likelihood of generating intermittent high-pressure contractions. Hohenfellner and colleagues elegantly evaluated the properties of gut smooth muscle layers (circular and longitudinal) of ileal and cecal segments in a canine model. The circular muscle layer of ileum was found to be most distensible, followed by the colonic circular and longitudinal ileal layers. The longitudinal layer of the colonic segment was relatively nondistensible (Hohenfellner et al, 1993). Studies in humans showed that the urodynamic characteristics of the ileum appear to be superior to those of the colon (Berghlund et al, 1987; Lytton and Green, 1989; Davidsson et al, 1992; Schrier et al, 2005; Chen et al, 2009). Stomach and sigmoid colon have been found to have particularly poor compliance and high pressures (Santucci et al, 1999). Schrier and colleagues found that neobladders made of ileum had larger capacity, lower filling pressures, lower maximum capacity pressures, and better compliance. The distal small bowel mesentery also tends to have the greatest mobility and generally reaches to the urethra without much difficulty. In patients with short ureteral length because of malignancy or other pathology of the ureters, an ileal pouch with a "tail" (such as the Studer) can be extended to reach all the way to the renal pelvis. A final advantage of ileum is the atrophy of the intestinal mucosa as it is exposed to urine over time. This results in decreased mucous production and decreased reabsorption of urinary electrolytes in the mature reservoir. Mucosal atrophy appears to be more reliable in small bowel than in large bowel reservoirs (Norlen and Trasti, 1978; Mills and Studer, 1999).

The primary disadvantage of using distal ileum lies in the potential loss of absorption of vitamin B₁₂. This segment may also have been unacceptably damaged by prior pelvic radiation or may be unavailable because of multiple prior bowel resections or inflammatory conditions such as Crohn disease. Whenever ileum is available, we preferentially use it for orthotopic diversion.

Bladder replacement using stomach has also been described, although it has not been a popular technique (Adams et al, 1988; Nguyen, 1991; Hauri, 1998; Lin et al, 2000). The primary advantage of gastric segments is that the gastric mucosa excretes chloride and hydrogen ions, effectively reversing the acidosis of renal insufficiency. The excreted acid from a stomach segment can also reduce the risk of bacterial colonization, and there is less mucous production. However, the disadvantage of using stomach is that compliance is worse than ileum and some patients will develop dysuria or hematuria from the excreted acid (Nguyen, 1991; Lin et al, 2000). Combining gastric and small or large intestinal segments can counteract some of these side effects and may be ideal from a purely metabolic standpoint (Lockhart et al, 1993). This construction can theoretically be performed in a patient with compromised renal function when continent diversion is contraindicated. It may also provide another option in a patient with prior high-dose pelvic radiation or multiple previous bowel resections. Few urologists have been trained in the surgical anatomy of the stomach, and most who perform a significant number of cystectomies currently rarely, if ever, use this type of diversion.

Isolation of the segment of bowel to be used for the diversion must be performed carefully to preserve blood supply to the pouch, as well as to the bowel anastomosis. If using ileum, one should avoid deep incision into the mesentery at the proximal bowel division to avoid compromising the blood supply to the reservoir. In addition, in patients who have had previous bowel resection it is important to take down the old anastomosis rather than choosing another site nearby because that could result in a poorly vascularized segment between the new and old bowel anastomoses.

Need to Prevent Reflux

The deleterious effect of vesicoureteral reflux in children is well accepted, especially in the face of infection. In the context of urinary diversion the importance of reflux was first identified in patients undergoing ureterosigmoidostomy (Clarke and Leadbetter, 1955; Wear and Barquin, 1973) and, subsequently, ileal conduit urinary diversion (Shapiro et al, 1975; Middleton and Hendren, 1976). It has been believed that the frequent long-term deterioration of renal function and upper tract changes seen in up to 50% of patients with ileal conduit urinary diversions by 15 years are the result of high-pressure reflux of infected urine (Clark et al, 1999; Madersbacher et al, 2003). Mean time to development of kidney problems in conduit patients is 5 years, and the incidence of such complications seems to increase steadily with time (Clark et al, 1999).

However, studies that have compared refluxing versus nonrefluxing urinary diversion have been limited, in general, by short follow-up, patient selection bias, retrospective design, or relatively small patient numbers. Richie and colleagues showed a protective effect of nonrefluxing anastomoses in a dog model (Richie et al, 1974). Kristjansson and colleagues found no difference in colon conduits with nonrefluxing anastomoses versus ileal conduits with refluxing anastomoses. However, continent diversions with antireflux techniques appeared to result in less upper tract scarring and bacteriuria (Kristjansson et al, 1995a, 1995b). Studies by both Elder and Hill showed that upper tract deterioration was common in both colonic and ileal conduits, although each had high rates of stomal stenosis and ureteroenteric stenosis (Elder et al, 1979; Hill and Ransley, 1983). Althausen showed better results using nonrefluxing colon conduits, but the follow-up in this study was only 3 years (Althausen et al, 1978). Song and Hautmann each found no differences in renal function or hydronephrosis in refluxing or nonrefluxing orthotopic neobladders in nonrandomized retrospective studies (Hautmann et al, 2006; Song et al, 2006). All of these studies were retrospective and nonrandomized and in general included relatively small numbers of patients.

With orthotopic diversion, most patients void by Valsalva maneuver with relaxation of the external sphincter. The resulting increase in pressure in the reservoir should be transmitted equally to the rest of the system, limiting any resulting back pressure even without an antireflux mechanism (Thoeny et al, 2002; Studer et al, 2006). However, free reflux into the upper tracts of the Studer pouch is often visible on cystogram with as little as 300 mL of filling, well within the typical voided volume of these patients. It is likely that there is some retrograde flow of urine in these patients at times. In patients who require intermittent catheterization to empty, such reflux could potentially occur at relatively high pressures when the reservoir is full. Finally, although symptomatic infections are uncommon (see later), it is not unusual for these patients to have asymptomatic bacteriuria, especially if they are doing self-catheterization. Steven and Poulsen reported 34% 3-year and 24% 5-year prevalence rates for bacteriuria in 166 men undergoing orthotopic reconstruction (Steven and Poulsen, 2000).

Medium- to long-term results with a refluxing type of reservoir such as the Studer pouch suggest that normal renal function and preserved upper tract anatomy are possible in the majority of patients (Thoeny et al, 2002; Perimenis et al, 2004; Minervini et al, 2005; Studer et al, 2006). Thoeny and colleagues examined long-term results in 76 patients with a Studer pouch with 5 or more years of follow-up and found preserved renal function and anatomy in 95% of the patients (Thoeny et al, 2002).

It is clear that any mechanism introduced to prevent reflux may also potentially cause upper tract obstruction. Initial experience with the intussuscepted Kock nipple valve showed that it provided reliable protection against reflux and seemed to have few drawbacks. However, as surviving patients were followed out to 10 years and beyond, it became clear that approximately 5% of patients experienced obstruction from stenosis of the afferent nipple valve, and an additional 5% developed stones on or extrusion of the afferent nipple valve (Stein et al, 1996). Afferent valve obstruction was often clinically silent. Patients who were not followed

carefully occasionally developed acute renal failure and bilateral hydronephrosis with significant renal damage, underscoring the need for careful lifetime follow-up in patients with urinary diversion. Similarly, ureteroileal obstruction with the antireflux Camey–Le Duc ureteral implantation technique has been reported to occur in 7% to 29%, compared with less than 3% for a direct ureteroileal anastomosis (Pitts and Muecke, 1979; Le Duc et al, 1987; Shaaban et al, 1992; Roth, 1997; Pantuck et al, 2000).

Abol-Enein and Ghoneim developed a serous-lined ureteral implantation technique with an ileal neobladder and reported their intermediate experience (mean follow-up of 38 months) in 450 patients. In this large series, 96% of upper tracts remained unchanged or improved; reflux was observed in only 3% of patients. Anastomotic ureteral stricture occurred in 3.8% of patients, an incidence similar to that of most refluxing ureteroileal anastomoses (Pantuck et al, 2000). The T pouch was designed building on this technique to provide protection from reflux while avoiding some of these complications of the Kock nipple valve. This is accomplished by preserving optimum blood supply to the tunneled ileal afferent limb segment while allowing the ureters to be directly implanted into the ileum, allowing for ureters that are dilated or must be divided high (Stein et al, 1998b; Stein and Skinner, 2006). With 33 months' median follow-up, renal function and anatomy were preserved in 90% of patients, with only 2% developing stenosis related to the afferent T limb during this time (Stein et al, 2004). In recent years the technique has been modified to avoid tapering the afferent limb in an attempt to further limit the development of late stenosis.

Shaaban and colleagues (2006) performed a small prospective randomized clinical trial evaluating whether prevention of reflux is beneficial. They studied 60 patients who all had normal renal function preoperatively and no hydronephrosis. In each patient one randomly chosen ureter was implanted in an antireflux manner (using an extraserosal tunnel), and the other was implanted directly into a small tubularized chimney on a standard W ileal neobladder. At 2 years' median follow-up, the researchers found more deterioration in the renal units drained with the antireflux technique, which resulted in five cases of documented obstruction, than in those with a direct refluxing anastomosis (Shaaban et al, 2006).

We recently completed a larger prospective randomized trial with 484 patients undergoing radical cystectomy randomized to receive either a Studer or T pouch urinary diversion. At 3 years there were no differences in renal function or urinary tract infections between the two groups. However, the patients with the T pouch were more likely to require diversion-related secondary procedures than those with the Studer construction (Skinner and Skinner, 2010; Skinner et al, 2012; Fahey et al, 2013).

As the overall medical and surgical therapy for bladder cancer improves and patients live longer after cystectomy and urinary diversion, placing them at further long-term risk for renal deterioration, reflux prevention may become a more important issue. The basic question remains whether any benefit in upper tract protection afforded by the antireflux technique outweighs the potential risk of upper tract obstruction from the antireflux technique itself in patients with bladder cancer. Further clarification of this question awaits the long-term results of these prospective randomized trials.

KEY POINTS: CHOICE OF BOWEL SEGMENT AND THE NEED TO PREVENT REFLUX

- Reservoirs made from ileum or combined ileum and colon appear to have the best physiologic properties for orthotopic diversion.
- Isolation of the segment of bowel to be used for the diversion must be performed carefully to preserve blood supply to the pouch and bowel anastomosis.
- The addition of an antireflux mechanism does not appear to be necessary for preservation of the upper tracts and prevention of infections, at least in the intermediate term.

General Perioperative Management

Perioperative management of patients undergoing cystectomy and orthotopic diversion is not significantly different than for patients undergoing other types of diversion. Preoperative history should focus on prior abdominal or pelvic surgery or radiation, current voiding patterns and continence, and general medical problems and social support, as well as patient priorities and preferences. If colon may be used for the diversion, a colonoscopy is recommended to rule out polyps or tumors.

There is no consensus on the ideal management of ureteral stents or catheters in patients undergoing orthotopic diversion. Most authors recommend the use of ureteral stents in the early postoperative period (Mattei et al, 2008). We use 8-Fr plastic pediatric feeding tubes or 7-Fr single-J urinary diversion stents and tie them to the urethral catheter so that they can be removed at the same time and the patient has fewer external bags to manage. They also use a 24-Fr stiff hematuria catheter, which facilitates routine irrigation of the pouch and is left in for approximately 3 weeks. The disadvantage of this system is the need to irrigate the catheter several times daily to ensure that the catheter does not plug up with mucus. Many surgeons alternatively use externalized ureteral stents brought through the skin and drained separately. The latter allow for less urine to pass through the pouch while it is healing and may decrease dependence on attentive nursing. A pelvic drain should be placed in every patient. In general, we leave the drain until the pouch has healed because of occasional late leakage if the catheter gets plugged at home.

Postoperative hospitalization in the past averaged approximately 8 to 10 days, primarily because of delayed feeding and postoperative ileus. We recently adopted an Early Recovery after Surgery (ERAS) protocol that has allowed routine discharge 3 to 5 days after surgery (Daneshmand et al, 2014). The protocol includes avoiding bowel preparation and nasogastric tubes, decreasing narcotic pain management (including epidural narcotics), instituting early feeding, and using a μ -opioid antagonist that blocks the effects of narcotics on the bowel. The μ -opioid antagonist alvimopan was recently demonstrated to reduce hospital stay in a double-blind, placebo-controlled randomized trial of 280 cystectomy patients (Lee et al, 2014). Other components vary among programs, and the individual contribution of each component to the overall pathway is less well studied (Karl et al, 2014).

When patients return at the 3-week postoperative mark, if there is minimal drainage from the drain (<100 mL during 24 hours), the catheter is removed, followed by the drain. Routine pouchograms or radiographic studies of the neobladder are not routinely performed unless a significant output from the drain is observed. Patients receive education throughout the perioperative period regarding catheter management, pelvic floor exercises, and proper voiding technique.

Surgical Techniques

A large number of modifications of the techniques presented next have been described in a small number of patients, and this is by no means an exhaustive list.

Ileal Reservoirs

Most ileal reservoirs use from 60 to 75 cm of terminal ileum, which is detubularized and folded in a variety of ways to attempt to create a spheric shape. Modifications primarily include variations in the exact folding technique and variations in management of the ureters, with or without an antireflux mechanism. In general, all reservoirs are closed with continuous absorbable suture. **The use of nonabsorbable suture and metal staples should be avoided because of the potential for stone formation (Stein et al, 1994b; Suriano et al, 2013).** Absorbable staples have been developed, and some authors have found them useful, although they tend to be somewhat bulky and awkward to use (Bonney and Robinson, 1990; Olsson et al, 1995; Montie et al, 1996).

The two most popular configurations around the world are the Hautmann W-neobladder (and its various modifications) and the Studer pouch neobladder. Both are relatively simple constructions and allow direct ureteroileal anastomosis, which has been shown to have the lowest risk of subsequent stricture. The T pouch and extraserosal tunnel techniques both provide an antireflux mechanism when that is felt to be advantageous.

Camey II

The Camey II orthotopic substitute (Camey, 1990) is a modification of the original Camey bladder substitute (Lilien and Camey, 1984), which was a simple segment of ileum anastomosed to the ureters and urethra. The modification includes detubularization and folding to eliminate peristaltic activity. A total of 65 cm of ileum is isolated, with an area of the ileum identified to reach to the region of the urethra in a tension-free manner. After the integrity of the bowel is restored, the mesenteric trap is closed and the isolated portion of ileum is opened along the antimesenteric border for the entire length, except the area previously identified for the urethral anastomosis. In this region, the ileal incision is directed toward the mesenteric border. The ileum is then placed in a transverse U orientation. The medial borders of the U are sutured together with a running absorbable suture. A fingertip opening is made in the pre-selected area for the ileourethral anastomosis, the entire ileal plate is brought down to the pelvis, and the urethral anastomosis is performed. The ureteroileal anastomosis is then performed via a Le Duc technique (Le Duc et al, 1987). The reservoir is completed by folding the ileal plate and suturing with a running absorbable suture. The ends of the U are anchored to the pelvic floor to reduce tension (Fig. 99-4). A modification of the Camey II has been described by Barre and colleagues (1996). This places the ileum in a Z configuration and reportedly has the advantages of shorter length requirements, improved reservoir capacity, and potentially improved functional (continence) results (Barre et al, 1996).

Orthotopic Kock Ileal Reservoir (Hemi-Kock)

The Kock ileal reservoir was first used as a continent cutaneous ileal reservoir incorporating intussuscepted nipple valves for both the afferent (antireflux) and efferent (continence) limbs (Kock et al, 1982; Skinner et al, 1984). This subsequently evolved into an orthotopic form of diversion in which the afferent intussuscepted limb was maintained to prevent urinary reflux (Fig. 99-5) (Ghoneim et al, 1987; Skinner et al, 1991). Skinner and colleagues performed more than 500 of these procedures from 1982 to 1995, with excellent continence and a low ureteroileal stricture rate of less than 3% (Skinner et al, 1988; Elmajian et al, 1996). Schreiter described an S-shaped modification of the orthotopic Kock ileal reservoir (Schreiter and Noll, 1989). With long-term follow-up, late complications associated with the afferent intussuscepted antireflux nipple developed in a small but significant number of patients (Stein et al, 1994a, 1996). These included stone formation on exposed staples (5%), stenosis of the afferent nipple ostium thought to be secondary to a compromised blood supply (4%), and extussusception or prolapse of the afferent limb (1%). These complications often occurred more than 10 years after construction of the reservoir and were clinically silent until the patient developed bilateral hydronephrosis or even renal failure (Stein et al, 1996). The technical difficulty of the intussuscepted nipple valve and the associated complications, along with the development of effective alternative techniques, has made this neobladder procedure primarily of historical interest.

Serosus-Lined Extramural Tunnel

Abol-Enein and Ghoneim demonstrated that an effective antireflux mechanism could be made by bringing the ureters into a reservoir through extramural serous-lined tunnels. These authors believed that the construction of an extramural serous-lined tunnel provides several advantages. Metallic staples or synthetic materials are not

Figure 99-4. Construction of the modified Camey II. A, The ileal loop is folded three times (Z shaped) and incised on the antimesenteric border. B, The reservoir is closed with a running suture to approximate the incised ileum. C, The urethral anastomosis is performed, and the ureters are implanted using a Le Duc antireflux technique.

Figure 99-5. Construction of the Kock ileal reservoir. A, A total of 61 cm of terminal ileum is isolated. Two 22-cm segments are placed in a U configuration and opened adjacent to the mesentery. The more proximal 17-cm segment of ileum will be used to make the afferent intussuscepted nipple valve. B, The posterior wall of the reservoir is then formed by joining the medial portions of the U with a continuous running suture. C, A 5- to 7-cm antireflux valve is made by removing the mesentery under that segment and then intussuscepting the afferent limb with the use of Allis forceps clamps. D, The afferent limb is fixed with two rows of staples placed within the leaves of the valve. E, The valve is then fixed to the back wall from outside the reservoir with additional surgical staples. F, After completion of the nipple valve, the reservoir is completed by folding the ileum on itself and closing it, leaving the most dependent end of the suture line open for the urethral anastomosis.

required. The serous-lined tunnel protects the implanted portion of the ureter from exposure to urine so that sound healing without scarring is ensured. Moreover, a relatively short segment of bowel is used, and the procedure is versatile and not technically difficult (Abol-Enein and Ghoneim, 1993, 1994). The authors updated their excellent results in 450 patients with this technique and demonstrated that the serous-lined extramural tunnel is an effective and durable antireflux technique, with more than 93% of patients having unidirectional, unobstructed urinary flow (Abol-Enein and Ghoneim, 2001).

A 40-cm ileal segment is isolated from the distal ileum and arranged in a W configuration. The antimesenteric border of the isolated intestine is opened, and the edges of the medial flaps are joined with a running absorbable suture. On either side, the serosal surface of the two lateral flaps are joined by a seromuscular continuous suture of silk (3-0). This forms two serous-lined intestinal troughs. Each ureter is laid down in its corresponding trough. A mucosa-to-mucosa anastomosis is performed with the spatulated ureter and the intestinal mucosa at the distal end of the trough. The mucosal edges on each side are then approximated over the reimplanted ureter. The anterior wall of the pouch is then closed in a side-to-side fashion. The suture line of the most dependent portion of the pouch close to the urethral stump is reopened to make a hole that will be anastomosed to the urethra (Fig. 99-6).

Good results with this technique have been reported by others (Papadopoulos and Jacobsen, 2001). A modification of this orthotopic substitute with a serous-lined extramural ureteral reimplantation technique has also been reported by Kato and colleagues (2001) with similar results. The primary disadvantage of this technique is the requirement for long ureteral length, inability to accommodate dilated ureters, and a possibly increased risk of ureteral strictures (Kato et al, 2001).

Figure 99-6. Construction of the serous-lined, extramural ileal neobladder (Ghoneim). A, A 40-cm segment of ileum is isolated and fashioned into a W configuration. B, The ileum is opened along the antimesenteric border for the entire length. C, The incised mucosa is joined in the middle with a running suture. The two lateral ileal flaps are joined by a seromuscular continuous suture to make the backing for the serous-lined ureteral tunnels. D, The spatulated ureters are laid into each trough, anastomosed to the intestinal mucosa, and stented. The tunnel is then closed over the implanted ureter. E, The anterior wall of the reservoir is formed by folding the ileum side to side. The reservoir is then anastomosed to the urethra.

Ileal Neobladder (Hautmann Pouch)

The Hautmann pouch ileal neobladder was developed by Hautmann and colleagues (Hautmann, 2010). This neobladder is an intentionally large-capacity, spheric (W configuration) ileal reservoir that is constructed in an attempt to optimize initial volume and potentially reduce nighttime incontinence. A segment of terminal ileum of approximately 70 cm is selected. The bowel is reconstituted, and the mesenteric trap is closed. The ileal section that reaches the urethra most easily is identified and marked with a traction suture along the antimesenteric border. The isolated bowel segment is then arranged in either an M or W shape and is opened along the antimesenteric border except for a 5-cm section along the traction suture where the incision is curved to make a U-shaped flap.

The four limbs of the M or W are then sutured to one another with a running absorbable suture. A small full-thickness segment of bowel is excised in the site for the urethral anastomosis, which is then performed with the sutures tied from inside the neobladder. Once the ileal neobladder is situated in the pelvis and the urethral sutures are tied, the ureters are implanted from inside the neobladder through a small incision in the ileum at a convenient site. The remaining portion of the anterior wall is then closed with a running absorbable suture (Fig. 99-7).

Initially Hautmann used an antireflux ureteral anastomosis as described by Le Duc and colleagues (Le Duc et al, 1987). However,

Figure 99-7. Construction of the Hautmann ileal neobladder. A, A 70-cm portion of terminal ileum is selected. The isolated segment of ileum is incised on the antimesenteric border. B, The ileum is arranged into an M or W configuration with the four limbs sutured to one another. C, After a buttonhole of ileum is removed on an antimesenteric portion of the ileum, the urethral anastomosis is performed. The ureteral anastomoses are performed using a Le Duc technique or direct implantation and are stented, and the reservoir is then closed in a side-to-side manner. As an alternative, the two ends of the W may be left slightly longer as a short chimney on either side for implantation of the ureters.

ureteroileal strictures were fairly common, and beginning in 1997 he modified this technique and now uses a freely refluxing, open end-to-side anastomosis implanted into short tubularized segments at each end of the W. This resulted in a decrease in the risk of ureteroileal stenosis from 9.5% to 1% (Hautmann, 2001; Hautmann et al, 2006).

This pouch has a larger initial capacity than the Studer pouch, which may assist in earlier continence. However, it may also result in an increased incidence of late urinary retention and increased electrolyte reabsorption from the pouch. Sevin has reported a modified Hautmann ileal neobladder in which only 40 cm of ileum is used to reduce these potential issues with acceptable clinical outcomes (Sevin et al, 2004). The classic configuration of the pouch also could not accommodate short ureters, but in the revised technique one or both ends of the W can be left long to anastomoses to one or both shortened ureters (Hollowell et al, 2000).

Studer Pouch

The ileal bladder substitute as initially described by Studer and colleagues used a long, afferent, isoperistaltic, tubular ileal segment. It is believed that the long segment functionally prevents vesicoureteral reflux when the patient voids by Valsalva maneuver (Studer et al, 1989, 1996). It is straightforward to construct and has become one of the most popular form of orthotopic diversion in the United States. The advantages of this bladder substitute include the simplicity of construction, the lack of a requirement for surgical staples, and the ability to accommodate short ureters. The reservoir portion uses the optimal double-folded U configuration as originally described by Kock (Kock et al, 1989). Studer's group reported on 480 of these procedures performed from 1985 through 2005 with excellent long-term results in terms of continence, preservation of renal function, and a ureteroileal stricture rate of less than 3% (Studer et al, 2006). The original description used a 20-cm afferent segment, with 40 cm used for the reservoir. In more recent years Studer has advocated using a somewhat shorter afferent ileal segment, with similar results (Studer et al, 2006).

The terminal portion of the ileum (54 to 56 cm long) is isolated approximately 15 to 20 cm proximal to the ileocecal valve. The distal mesenteric division is made along the avascular plane between the ileocolic artery and terminal branches of the superior mesenteric artery. The proximal mesenteric division, however, is short and provides a broad vascular blood supply to the reservoir. In addition, a small window of mesentery and 5 cm of small bowel proximal to the overall ileal segment are discarded, ensuring mobility to the pouch and small bowel anastomosis. Bowel anastomosis is performed using staplers.

The Studer pouch is created from 40 to 44 cm of distal ileum with each limb of the U measuring 20 to 22 cm and a proximal 15-cm segment of ileum used as the afferent limb. If ureteral length is short or compromised, a longer afferent ileal segment (proximal ileum) may be used. The proximal end of the isolated afferent ileal segment is closed with absorbable suture. The isolated ileal segment is opened about 2 cm away from the mesentery, and the incised ileal mucosa is then oversewn with two layers of a running 3-0 polyglycolic acid suture (Fig. 99-8).

T Pouch Modification

In an effort to preserve an antireflux mechanism but avoid the potential long-term complications seen with the Kock nipple valve, as well as to allow for more flexibility in managing the ureters, Stein and Skinner developed the T pouch as a modification of Ghoneim and Abol-Enein's serous-lined ureteral tunnel and updated their results with intermediate follow-up of 209 patients (Stein et al, 2004; Stein and Skinner, 2006). The technique is modified for construction of an antirefluxing afferent limb in the T pouch. The ileum is divided between the proximal afferent ileal segment and the 44-cm segment, and the antireflux mechanism is created by

anchoring the distal 3 to 4 cm of the 15-cm afferent ileal segment into the serosal-lined ileal trough formed by the base of the two adjacent 22-cm ileal segments. Mesenteric windows of Deaver are opened between the vascular arcades on the T limb. A series of 3-0 silk sutures is then used to approximate the serosa of the two adjacent 22-cm ileal segments at the base of the U, with the sutures being passed through the previously opened windows of Deaver to anchor the afferent limb (Fig. 99-8D, E1, and E2). Initial descriptions of the T pouch included tapering the distal portion of the afferent segment after it had been fixed into the tunnel to decrease its diameter and decrease the risk of reflux. However, these efforts appeared to be associated with occasional late stenosis of the end of the afferent valve. In 2004 the author (E.C.S.) stopped tapering the distal afferent limb with improved results.

When the incision in the U limb of reservoir reaches the level of the afferent ostium, it is extended directly lateral to the antimesenteric border of the ileum and carried upward (cephalad) to the base of the ileal segment. This incision provides wide flaps of ileum that are brought over the afferent ileal segment and sutured in two layers to create the antireflux mechanism in a flap-valve technique. An interrupted mucosa-to-mucosa anastomosis is then performed between the ostium of the afferent ileal limb and the incised intestinal ileal flaps with 3-0 polyglycolic acid sutures (see Fig. 99-8E2). The rest of the neobladder is constructed in the same fashion as the Studer pouch.

Colon and Ileocolic Pouches

Orthotopic neobladders constructed completely of colon are a good option for patients with multiple previous small bowel resections or who have diseased ileum. Colon segments are less distensible than ileal segments and may be more likely to produce higher-pressure waves causing incontinence (Khafagy et al, 2006). As a consequence, initial volume should be larger than for an ileal pouch. Combined colon and ileal segments can mitigate this problem.

Orthotopic Mainz Pouch (Mainz III)

The Mainz ("mixed augmented ileum and cecum") pouch was initially described as a continent catheterizable reservoir that was subsequently modified into an orthotopic neobladder (Thuroff et al, 1986; Eisenberger et al, 1999). A 10- to 15-cm segment of cecum, in continuity with a 20- to 30-cm segment of ileum, is isolated. An ascending ileocolostomy is performed. The entire segment of bowel is opened along the antimesenteric border, sacrificing the ileocecal valve. The bowel is placed in a W configuration, with the first limb of the W made from cecum and the other limbs made from the ileum. The adjacent three limbs are sutured together with an absorbable suture, forming the posterior plate of the reservoir.

At the cephalad portion of the cecum, tunneled ureterocolonic anastomosis is performed. A buttonhole incision is made in the cecum at the base of the reservoir, and a ureterocolonic anastomosis is performed. After this, the reservoir is closed side to side with absorbable suture (Fig. 99-9).

Le Bag Pouch

The Le Bag ileocolonic bladder substitute was initially described by Light and Engelmann. A 20-cm segment of ascending colon and a corresponding length of terminal ileum are isolated, and bowel continuity is restored. The antimesenteric border is incised for the entire length of the colon and ileum to make two flat sheets (one small and one large bowel). These sheets are then sewn to each other to form the posterior plate. Initially, in the early experience with this neobladder, the incision in the small bowel commenced 2 inches from the cut end so that this intact tube of ileum could be anastomosed end to end to the urethra. This technique was subsequently modified because the small intact ileal segment was thought to promote urinary incontinence because of peristalsis. After this, the entire length of small bowel was incised (Light and Engelmann,

Figure 99-8. Construction of the Studer neobladder (modified). A, Designated segments of terminal ileum for construction of the orthotopic Studer pouch ileal neobladder. Note that the distal mesenteric division is made between the ileocolic and terminal branches of the superior mesenteric artery, which extends into the avascular plane of the mesentery. In addition, a small window of mesentery and a 5-cm segment of proximal small bowel are discarded to allow mobility to the pouch and small bowel anastomosis. B, The Studer pouch is constructed from an isolated 44-cm ileal segment (placed in an inverted U configuration), which forms the reservoir portion of the pouch, and a proximal 15-cm segment of ileum to form the afferent limb. The two 22-cm ileal segments are opened 2 cm adjacent to the mesentery beginning at the apex and carried upward to the ostium of the afferent segment. C, The previously incised ileal mucosa is then oversewn with two layers of a running 3-0 polyglycolic acid suture starting at the apex and running upward to the afferent limb. The reservoir is then closed by folding it in half in the opposite direction to which it was opened. D, Construction of the antireflux mechanism in the T pouch. The ileum is divided between the proximal afferent ileal segment and the 44-cm segment. The dotted line depicts the incision line on the U limbs. Mesenteric windows of Deaver are opened between the vascular arcades adjacent to the serosa. Placement of small Penrose drains through each mesenteric window helps facilitate passage of sutures. The distal 3 to 4 cm of the afferent ileal segment is anchored into a serosal-lined ileal trough formed by the base of the two adjacent 22-cm ileal segments, using 3-0 silk sutures. E1, The previously anchored distal 3- to 4-cm afferent ileal segment is tapered over a 30-Fr catheter on the antimesenteric border. The incision of the bowel provides wide flaps of ileum that covers the tapered distal afferent ileal segment to form the antireflux mechanism in a flap-valve technique. E2, A mucosa-to-mucosa anastomosis is performed between the ostium of the afferent segment and the edges of the ileal flaps using interrupted 3-0 polyglycolic acid suture. The mucosal edges of the ileal flaps are brought over the tapered distal portion of the afferent ileal segment and sewn using a continuous 3-0 polyglycolic acid suture. F, Once the reservoir is folded in half, the anterior wall is closed with a two-layer 3-0 polyglycolic acid suture that is watertight. Note that the anterior suture line is stopped just short of the (patient) right side to allow insertion of an index finger, which will become the neobladder neck. Conversely a new buttonhole can be created at the most dependent portion of the pouch. G, Each ureter is spatulated and a standard bilateral end-to-side ureteroileal anastomosis is performed using interrupted 4-0 polyglycolic acid suture. H, The reservoir is anastomosed to the urethra using the previously placed urethral sutures. (Copyright 2012 Laramie Studio. Used with permission.)

Figure 99-9. Construction of the Mainz ileocolonic orthotopic reservoir. A, An isolated 10 to 15 cm of cecum in continuity with 20 to 30 cm of ileum are isolated. B, The entire bowel segment is opened along the antimesenteric border. An appendectomy is performed. C, The posterior reservoir is closed by joining the opposing three limbs together with a continuous running suture. D, An antireflux implantation of the ureters through a submucosal tunnel is performed and stented. E, A buttonhole incision in the dependent portion of the cecum is made to provide for the urethral anastomosis. F, The reservoir is closed side to side with a cystostomy tube and the stents exiting.

1986; Light and Marks, 1990; Kolettis et al, 1996), and the urethra was anastomosed, end to side, to the cecum. The ureters are then brought into the colonic segment and implanted within the reservoir, and the neobladder is closed anteriorly (Fig. 99-10).

A modified version of the Le Bag ileocolonic neobladder has been reported by Baniel and Tal in which a Studer-like ileal chimney is incorporated as the afferent limb (Baniel and Tal, 2004).

Right Colon Pouch

An orthotopic substitute using the right colon without ileum has been reported (Goldwasser et al, 1986; Mansson and Colleen, 1990; Goldwasser, 1995; Mansson et al, 2003). The entire right colon and cecum are isolated, and a transverse ileocolonic

anastomosis is performed to provide bowel continuity. The ileal stump at the ileocecal valve is closed with a running absorbable suture. The colonic segment is then opened along the anterior taenia, leaving the proximal 2 to 3 inches of cecum intact. An appendectomy is performed, and the ureters are implanted in an antireflux fashion within the reservoir. The colon is then folded in a Heineke-Mikulicz manner and closed with a running absorbable suture. The ureterocolonic anastomosis is then performed.

Sigmoid Pouch

Patients who are candidates for radical cystectomy often have a redundant sigmoid colon, which is readily available for use. The only concern is the potential compromise of the vasculature of the distal colon segment because of interruption of branches of the internal iliac artery during the cystectomy. It is important, therefore, to maintain as much of the vascular supply to both ends of the bowel anastomosis as possible. Some patients will complain of frequent stools or rectal urgency for a period of time after sigmoid colectomy.

The use of the sigmoid in construction of an orthotopic substitute was initially described by Reddy and Lange (Fig. 99-11). A 35-cm portion of descending colon and sigmoid is isolated and arranged in a U configuration on the basis of the inferior mesenteric artery. The medial taenia of the U is incised down to an area just short of the urethral anastomosis. The incised medial limbs of the U are then brought together with an absorbable suture. Ureteral implantation is performed in a tunnel antireflux fashion. A small button of colon is removed from the most dependent portion of the reservoir, and the urethroenteric anastomosis is performed. The reservoir is then closed side to side (Reddy and Lange, 1987).

A modification of this technique was reported by DaPozzo and colleagues in which the entire bowel is detubularized and then folded in a Heineke-Mikulicz fashion to provide a more spheric reservoir (DaPozzo et al, 1994).

Use of Minimally Invasive Techniques for Orthotopic Diversion

Over the past 15 years a number of surgeons have performed cystectomy using laparoscopic or robotic-assisted techniques (Gill et al, 2002; Pruthi and Wallen, 2008; Stephenson and Gill, 2008; Wang et al, 2008; Yuh et al, 2008). Initial attempts to perform the diversion completely intracorporeally were fraught with difficulty, and the procedure was gradually replaced with extracorporeal construction after removal of the bladder through a small midline incision (Haber et al, 2008). This has allowed construction of continent diversions, both cutaneous and orthotopic. The Studer ileal neobladder has been the most popular because of ease of mobilization of the segment and simpler bowel anastomosis with a low abdominal incision. In the case of orthotopic neobladders, some authors then re-establish the pneumoperitoneum and use robotic assistance to complete the urethral anastomosis. Others perform the anastomosis in an open fashion (Pruthi and Wallen, 2008).

Postoperative recovery in most series has only been modestly improved compared with open series, with longer operative times but decreased blood loss. Some series have reported reduced ileus and shorter hospital stay (Haber et al, 2008; Huang et al, 2008; Wang et al, 2008; Ng et al, 2010; Nix et al, 2010), but these were generally selected patients. Other unselected large series have shown that postoperative complications were equivalent or even increased compared with open series (Yuh et al, 2012; Messer and Parekh, 2013; Raza et al, 2013). Recently the concept of constructing the neobladder intracorporeally has been revived in an attempt to improve recovery (Goh et al, 2012) but this is a technically difficult procedure even in the hands of surgeons with extensive robotic experience. Robotic cystectomy and urinary diversion are covered extensively in Chapters 96 and 100.

Figure 99-10. Construction of Le Bag (ileocolonic) orthotopic reservoir. **A**, A total of 20 cm of ascending cecum and colon, with a corresponding length of adjacent terminal ileum, is isolated. The bowel is opened along the entire antimesenteric border, and the two incised segments are then sewn to each other. This forms the posterior plate of the reservoir. **B**, This reservoir is folded and rotated 180 degrees into the pelvis with the most proximal portion of the ileum (2 cm nondetubularized) anastomosed to the urethra. **C**, Modification is performed with complete detubularization of the bowel segment, which is then anastomosed to the urethra. RESULTS AND COMPLICATIONS OF ORTHOTOPIC URINARY DIVERSION

Early and Late Complications

A complete discussion of the early complications of radical cystectomy and diversion is outside the scope of this chapter. Complications of radical cystectomy and diversion are common, and many are severe and potentially life-threatening (Konety et al, 2006; Quek et al, 2006; Ali-El-Dein et al, 2008; Shabsigh et al, 2009; Hautmann et al, 2010, 2011). Early complications including bleeding, thrombotic events, infection, and cardiovascular and pulmonary complications are not directly related to the urinary diversion and do not appear to be different in patients undergoing different types of diversion. Gastrointestinal complications are also common after cystectomy and are at least partially related to the need for a bowel anastomosis, which is common to all types of diversion. Similarly, urine leak and ureteral complications are possible with any type of diversion. A number of authors have shown that the overall rate of complications, hospital stay, and reoperation rates are not increased by use of continent diversion compared with ileal conduit diversion (Benson et al, 1992; Gburek et al, 1998; Parekh et al, 2000a).

Urine leaks may be more common in continent diversion than in conduits because of the long suture lines, but with good catheter drainage and properly managed stents and drains these usually resolve with observation alone as long as a urinoma does not form. If a patient has an undrained leak, an attempt at percutaneous drainage and/or bilateral nephrostomy tube placement is preferable to open surgical repair. The latter is extremely difficult during the first few weeks after the initial surgery and is likely to be complicated by enterotomies and a risk of fistula formation. In our

experience approximately 5% of patients require some sort of percutaneous drain or nephrostomy tube placement during the early postoperative period to manage these problems.

Both early and late complications may also be influenced by other factors such as prior radiation therapy, diabetes, and other comorbidities. Late complications are also influenced by tumor recurrence and the use of adjuvant or salvage systemic chemotherapy or radiation, and these causes may be difficult to separate out from causes related to the surgery. Late complications not directly related to the diversion include bowel obstruction, ventral hernia, thrombotic events, and cardiovascular problems common to patients in this age group. Hautmann has made the point that most late complications increase with time and are best described using Kaplan-Meier curves rather than as simple percentages (Hautmann et al, 2011). Ventral hernias are quite common and may be in part related to the need for increased abdominal pressure to empty the neobladder. The poor fascial strength associated with advanced age and smoking undoubtedly contributes to this risk as well.

The primary late complications of orthotopic diversion that are directly related to the diversion itself include incontinence, urinary tract infection, ureteroileal or afferent limb obstruction, urethral stricture, upper tract and pouch stones, vaginal fistula, and pouch rupture. Other than incontinence, these complications tend to be less common in orthotopic diversion than in continent cutaneous diversion, and many if not most can be managed by endoscopic procedures and rarely require open surgical revision (Rowland et al, 1995; Hautmann et al, 2011).

Although symptomatic urinary infections do occur, asymptomatic colonization of the neobladder with bacteria is also very common, although less common than in continent cutaneous diversion unless the patient is on intermittent self-catheterization

Figure 99-11. Construction of the sigmoid (Reddy) neobladder. **A**, A 35-cm segment of descending and sigmoid colon is isolated and folded into a U shape. **B**, The colon is incised along the medial taenia down to a point a few centimeters short of the entire colon. A buttonhole is made in the caudal portion of the colon that is later anastomosed to the urethra. **C**, The medial portions of the U are sewn together, and a tunneled ureterocolonic anastomosis is performed. **D**, The colonic pouch is closed by folding the reservoir side to side, and it is anastomosed to the urethra.

(Suriano et al, 2008). Wood and colleagues looked at 66 patients undergoing orthotopic refluxing ileal neobladder, 11 of whom (17%) were doing intermittent self-catheterization. Positive urine cultures were found in 39% (Wood et al, 2003). Symptomatic urinary tract infections are unusual after the initial 90-day postoperative period. Hautmann and colleagues found a cumulative risk of febrile infections of only 5.7% in 923 patients undergoing ileal neobladder with median follow-up of 72 months. Infections were most common in the first year and occurred in 13.6% of those with poor emptying compared with only 3.4% in those who emptied well (Steven and Poulsen, 2000; Hautmann et al, 2011). An effort to sterilize the urine with culture-specific antibiotics in the initial postoperative period after the catheter has been removed is often successful. However, after that initial attempt, treatment of asymptomatic bacteriuria is likely to simply encourage development of resistant organisms. If local symptoms suggest an infection, it should be confirmed whenever possible by a culture in this patient population. A patient who develops a febrile infection after the initial few months should be evaluated for possible upper tract obstruction and incomplete emptying.

Pouch perforation is rare in continent diversion in general, especially in orthotopic diversion because outlet resistance is usually low. The risk may be increased in patients who have had previous radiation therapy. It is a potentially life-threatening complication when it occurs. We have seen at least two deaths caused by pouch perforation of an orthotopic diversion that was unrecognized when the patients were admitted to an outside hospital. Patients with a perforation typically have acute abdominal pain and distention, often with signs of sepsis. CT cystogram is usually diagnostic. In general, these patients should be managed with exploration and repair, although conservative management with percutaneous drains has been described (Mansson et al, 1997; Singh and Choon, 2004; Hautmann et al, 2013).

The rate of ureteroileal stricture is identical to that in ileal conduit diversion, and is influenced by the type of anastomosis. The direct end-to-side Leadbetter or the combined Wallace anastomoses with interrupted fine absorbable sutures have been shown to have the lowest risk of stricture, approximately 3% to 6% (Pantuck et al, 2000; Hautmann et al, 2011). Obstruction from an antireflux valve has been seen in both hemi-Kock pouches and in the extraserosal tunneled afferent limb of the T pouch (Stein et al, 1996, 2004). These may be clinically silent until the patient develops bilateral hydronephrosis or even renal failure. Diagnosis may be suspected on CT or ultrasonography and can be confirmed on retrograde pyelography or antegrade nephrostogram. CT scans will often be misinterpreted by radiologists or urologists unfamiliar with the anatomy and/or the specific type of neobladder. The obstructing antireflux segment may be managed by endoscopic incision of the valve mechanism. It can be technically challenging to find the afferent limb in some cases, and special techniques may be necessary to catheterize and incise it (Dunn et al, 2007).

Pouch stones were very commonly seen in the Kock neobladder because of the use of surgical staples to maintain the intussuscepted nipple valve, with the incidence increasing steadily with time (Stein et al, 1996). Stones have been rare in the Studer and Hautmann neobladders, which are made entirely with absorbable suture (Studer et al, 2006; Hautmann et al, 2011). Recently several authors have advocated use of a metal GIA stapler to speed up the construction of an ileal neobladder. In one such series of 50 patients, stones were found in 6% of patients with only 20 months' median follow-up (Fontana et al, 2004; Barbalat et al, 2012). It is predictable that the incidence of such stones will increase with more follow-up, and although they can be managed endoscopically this carries significant cost in both money and inconvenience for the patients and may lead to further complications (Suriano et al, 2013).

Pouch-vaginal fistula is a unique complication of orthotopic neobladder in women that can be quite difficult to repair. The reported incidence in larger series is 5% to 10%, and the risk is increased if a portion of the anterior vaginal wall is excised along with the cystectomy specimen and in irradiated patients (Ali-El-Dein et al, 2008; Granberg et al, 2008). Prevention methods include leaving the vagina intact whenever it is safe from an oncologic standpoint, careful watertight closure of the vaginal cuff when it is opened, and placement of an omental flap between the vagina and neobladder, secured to the perivaginal tissue on either side of the urethral anastomosis (Stein and Skinner, 2006). In the early postoperative period any concern about vaginal urinary leakage should be evaluated with a lateral cystogram before removal of the catheter. Fistula should also be ruled out in any woman with persistent significant incontinence after the first few months of recovery. This is most easily done with a careful pelvic examination and with methylene blue instilled into the neobladder if necessary.

Beyond the initial few weeks a pouch-vaginal fistula is unlikely to heal spontaneously or with catheter drainage or percutaneous nephrostomy tubes alone. Repair may be attempted transvaginally, although reported success varies (Rapp et al, 2004; Smith, 2005; Ali-El-Dein et al, 2008; Ali-El-Dein and Ashmallah, 2013). Repair may ultimately require transabdominal exploration or even conversion to a cutaneous form of diversion.

Continence

In evaluating the continence results and clinical outcomes of various series of cystectomy and orthotopic neobladders, several considerations must be kept in mind. The prevalence and severity of urinary incontinence may be influenced by a number of variables including age and gender of the patients, prior treatments (such as radiation or prostate surgery), surgical techniques, and surgeon experience. In addition, the definitions of continence, the techniques used to collect the information (e.g., chart review, telephone interview, or anonymous validated questionnaire), and the length and diligence of follow-up have varied tremendously among different reports (Thuroff et al, 1996; Hautmann et al, 2013). Although there is general consensus that the ideal tool for studying functional outcomes is a validated patient-completed questionnaire, all the tools available today have significant drawbacks. The widely used Bladder Cancer Index (BCI) was developed to be applicable to all types of urinary diversion. It captures urinary leakage but not details such as the severity of incontinence or pad use (Gilbert et al, 2007). Only a few reports have used questionnaires such as these to evaluate neobladder patients (Stein et al, 2009; Jentzmik et al, 2012; Ahmadi et al, 2013). **In summary, one should use caution in attempting to compare continence results from different series of patients with orthotopic diversion.** We have summarized results from some of the largest series in Tables 99-1 and 99-2.

Common observations from series of patients undergoing orthotopic diversion include a gradual period of improvement in daytime continence over the first 6 to 12 months with a slower improvement in nighttime continence even into the second year. In general, patients with orthotopic neobladders can achieve very good daytime continence. In a pooled analysis of 2238 patients with various forms of orthotopic neobladder, daytime incontinence was reported in an average of only 13% of patients. Risk factors for daytime incontinence included advanced age of the patient (older than 65 years), use of colonic segments, and in some series lack of nerve-sparing techniques. Other series have identified hysterectomy in women and diabetes as a risk factor for worse continence results (Steers, 2000; Kessler et al, 2004; Anderson et al, 2012; Ahmadi et al, 2013).

Nighttime incontinence remains one of the most bothersome sequelae of neobladders, occurring in 7% to 70% of patients (Steers, 2000). Most series report that 50% to 75% of patients have good nighttime continence (see Tables 99-1 and 99-2). Nocturnal incontinence after orthotopic reconstruction results in part from the absence of neurologic feedback and sphincter detrusor reflex, as well as decreased sphincter tone at night. There is also initially an excess of urine production at night with an inability to concentrate the urine and a reversal of the normal antidiuretic effect of nighttime dehydration because of secretion of water by the bowel mucosa, which decreases with time (El Bahnasawy et al, 2000). In elderly patients there is also a physiologic nocturnal diuresis associated with increasing age. The frequency and amount of urinary leakage at night is also dependent on how often the patient wakes to urinate. Instructing the patient to completely empty immediately before bedtime and to awaken two or three times with the assistance of an alarm clock if necessary may significantly reduce nighttime incontinence. We and others have observed that nighttime incontinence may improve as late as 24 months after surgery, and it is not a cause of major disturbance in quality of life for most patients (Elmajian et al, 1996; Granberg et al, 2008).

Kessler and colleagues assessed various factors influencing urinary continence after radical cystectomy and ileal orthotopic bladder substitution in 331 male patients. In a multivariate analysis, the time to achieve daytime continence and the ultimate rate of success were significantly higher in patients younger than 65 and in those with attempted nerve-sparing techniques. Older men and those with diabetes gained continence more slowly (Kessler et al, 2004). There are currently no randomized trials evaluating the importance of nerve-sparing, and all retrospective studies suffer from significant selection bias.

In women, preservation of the uterus may significantly affect the functional results of neobladder construction. Anderson and colleagues retrospectively reviewed 49 women who underwent cystectomy and neobladder procedures. Of the women, 31% had had a prior hysterectomy, 29% underwent hysterectomy at the time of cystectomy, and 40% had the uterus preserved. Women with the uterus preserved had better daytime continence (Anderson et al, 2012). Ali-El-Dein also reported on a small group of women who underwent uterine-sparing cystectomy with excellent short-term results (Ali-El-Dein et al, 2013). There is also suggestion that sexual function may be better preserved with this approach (Zippe et al, 2005; Bhatt et al, 2006).

Decreased urethral sensitivity has been proposed as a potential factor contributing to urinary incontinence after radical cystectomy and orthotopic diversion. It has been suggested that conscious or unconscious sensation of urine leakage in the membranous urethra may normally produce either a reflex or voluntary contraction with increased tone of the external urethra (Kessler et al, 2007). This may be impaired in some patients with an orthotopic diversion. This reflex may also diminish with age and contribute to gradually decreasing continence in some individuals after orthotopic reconstruction (Hugonnet et al, 1999; Madersbacher et al, 2002). To some degree this worsening continence with age might be offset by the lack of problems related to prostatic enlargement, detrusor hypertrophy, and overactive bladder, all of which are common in elderly patients.

Ahmadi and colleagues recently reported on a group of 263 male patients without prior radiation who were at least 12 months out from a cystectomy and neobladder (Studer or T pouch). They were mailed the validated BCI with some additional questions designed to elucidate the types and degree of wetness of pads and the impact of mucous leak. Response rate was 68%, and 139 of 179 responders used pads at least sometime, half of whom used them both day and night. Forty-seven percent used pads in the day, with a third of those using a small pad or minipad, and almost half found that the pad was usually dry or only slightly wet. Nighttime use was 72%, with most using a medium or heavy pad. Older age and diabetes correlated with worse outcomes. The degree of incontinence and the urinary function scores on the BCI did not correlate well with the degree of bother from these symptoms, which was generally low (Ahmadi et al, 2013). Stein and colleagues previously reported results using the same questionnaire in 56 women. They found that 23% had frequent leakage or no control during the day and 34% during the night, with 61% requiring self-catheterization at least once daily. These results may more accurately reflect the true patient experience compared with reports from chart reviews.

The evaluation and management of urinary incontinence after orthotopic diversion should be delayed until the neobladder has had time to expand. This may take 6 months to a year after surgery (Grossfeld et al, 1996; Studer et al, 2006; Granberg et al, 2008). Physical therapy with biofeedback focused on the pelvic floor muscles may help some patients attain initial continence (Parekh et al, 2003). Urodynamic investigation may be indicated to ensure adequate capacity, without pressure waves, especially if colon is used for the neobladder. If reduction in maximal urethral closure or low Valsalva leak pressure is demonstrated, transurethral injection of bulking agents may be considered, but it has had only marginal results in our experience. Alternatively, in men an artificial urinary sphincter or urethral sling can be considered and may provide a more definitive treatment (Simma-Chiang et al, 2012). In women, although injection of urethral bulking agents provides a minimally invasive approach with some positive results (Tchetgen et al, 2000), it is best used for women with minimal symptoms of incontinence, with overall success rates below 50% and with less than optimally durable responses (Wilson et al, 2004). Newer agents that do not absorb over time may have improved results. Pubovaginal sling procedures for incontinence may be more effective than bulking agents in women with incontinence after orthotopic reconstruction; however, most of these patients will subsequently need to perform intermittent catheterization. It is important to note that one should avoid blind passage of needles or sling

material into the pelvis in these patients because of a high risk of injury to the pouch or a loop of bowel stuck to the pubic symphysis. Use of infrapubic bone anchors or a prepubic approach may provide the safest surgical options (Quek et al, 2004).

Urinary Retention

Failure to empty or urinary retention (also often called *hypercontinence*) has been reported in 4% to 25% of patients undergoing orthotopic reconstruction and is much more common in women than in men (Steers, 2000; Nagele et al, 2006). Stein and colleagues, using chart review, reported that 25% of 209 patients with an orthotopic T pouch required at least occasional intermittent catheterization (20% of men and 43% of women) (Stein et al, 2004). Later, in one of the few studies using an anonymous patient questionnaire, 61% of 58 women required self-catheterization at least sometimes, and 39% required self-catheterization routinely to void (Stein et al, 2009). In the companion study of 179 male patients from the same institution, 9.5% used self-catheterization at least sometimes, but only 1 patient could not urinate at all without catheterization (Ahmadi et al, 2013). Although these types of studies are felt to more accurately reflect patient experience than chart review, they do suffer from the response bias inherent in mailed questionnaires.

Patients with incomplete emptying may have acute retention but more often have urinary infections or the new onset of overflow incontinence on presentation. They may also be discovered on routine follow-up with a palpable suprapubic mass, or distended reservoir or new-onset hydronephrosis on imaging. The development of retention may occur early but is often a late event, so the reported rates are heavily influenced by the length of follow-up of the series. Risk factors for urinary retention in patients with an orthotopic reservoir include the use of excessive intestinal length for the reservoir (>60 cm of ileum) and the use of prostate-sparing or nerve-sparing surgical procedures (Steers, 2000; Steven and Poulsen, 2000; Stein et al, 2004; Ji et al, 2010). Some authors have suggested that the location of the urethral anastomosis in the neobladder may contribute to retention in men because of folding of the neobladder (Thurairaja and Studer, 2008), but our experience using the end of the suture line for the urethral anastomosis in an ileal neobladder has resulted in a similarly low incidence of retention (Stein et al, 2004; Ahmadi et al, 2013). **Actual stricture of the neobladder-urethral anastomosis is rare.** In the series from Ulm with 923 patients and 72-month median follow-up, such strictures developed in only 11 patients (1.2%) in the absence of tumor recurrence. More distal urethral strictures developed in an additional 8 patients (Hautmann et al, 2011).

Rectal or vaginal examination and cystoscopy should be performed in patients who develop retention, to rule out a urethral anastomotic stricture or tumor recurrence. Urinary retention is best managed by intermittent self-catheterization (Steers, 2000). Pharmacologic intervention for patients with urinary retention does not appear to be an effective measure to improve this voiding dysfunction. Biofeedback training in pelvic floor relaxation may be helpful, and some authors have suggested that many of these patients have a flap of mucosa causing the obstruction that may be incised endoscopically with good effect (Thurairaja and Studer, 2008). Others have not found this to be a common cause of retention (Simon et al, 2006). Patients should be advised during the first few years of follow-up of the importance of adequate emptying and the need to consciously relax the external sphincter along with using Valsalva pressure during voiding.

A significant number of patients with orthotopic reservoirs will develop abdominal wall or incisional hernias postoperatively. In the series from Ulm the estimated risk by Kaplan-Meier analysis was 4% at 5 years and 6% by 10 years (Hautmann et al, 2011). In a prospectively followed patient population, it was as high as 13% at 3 years (Skinner, unpublished data). These fascial defects will reduce the efficiency in completely evacuating the neobladder by reducing the ability to effectively increase intra-abdominal pressure. These hernias should be identified and surgically repaired.

In women it appears that posterior prolapse of the pouch may contribute to late retention, and posterior support by means of omental flaps and sacrocolpopexy has been advocated (Ali-El-Dein et al, 2002; Stenzl and Höltl, 2003; Lee et al, 2004; Stein and Skinner, 2004). Ali-El-Dein and colleagues elegantly studied the possible causes of chronic retention after radical cystectomy and orthotopic bladder substitution in women. A total of 136 women underwent a standard radical cystectomy and orthotopic substitution, with 100 patients evaluable at a mean follow-up of 36 months. Overall, 95% of the women were continent during the day, 86% were continent at night, 2% were completely incontinent, and 16% were in chronic retention. Video-urodynamics showed that retention appeared to be mechanical in nature; the pouch has fallen back in the wide pelvic cavity, resulting in acute angulation of the posterior pouch-urethral junction. In addition, herniation of the pouch wall through the prolapsed vaginal stump was observed in most patients. Pelvic floor electromyography demonstrated complete pelvic floor silence during voiding, suggesting that urinary retention was not related to a neurogenic cause. The authors suggested that transposition of the omentum behind the reservoir, suturing of the peritoneum on the rectal wall to the vaginal stump, suspension of the vaginal stump by the preserved round ligaments, and suspension of the pouch near the dome to the back of the rectus muscle at cystectomy would help reduce the incidence of chronic retention (Ali-El-Dein et al, 2002). We have routinely performed a formal sacrocolpopexy suspension of the vaginal apex to the sacrum, but that alone has not eliminated retention. Preservation of the uterus and its ligament support structures may significantly reduce the risk of retention in women and should be considered when feasible (Anderson et al, 2012; Ali-El-Dein et al, 2013).

KEY POINTS: CONTINENCE AND URINARY RETENTION

- Daytime continence develops gradually over 3 to 6 months in most patients and is ultimately achieved in 80% to 90% of both male and female patients.
- Persistent nocturnal incontinence is common, observed in 20% to 50% of patients. Nocturnal continence may continue to improve beyond 12 months from surgery.
- Factors influencing continence rates include age, intestinal segment used, and possibly the application of a nerve-sparing technique.
- Failure to empty or urinary retention has been reported in 4% to 10% of men and 20% to 60% of women.

Follow-up for Patients with Orthotopic Diversion

There is no consensus on the ideal follow-up regimen for patients with orthotopic diversion. Imaging techniques include intravenous urography (rarely performed today), CT urography, magnetic resonance imaging, and ultrasonography. Physicians in the United States tend to depend more on radiographic imaging, whereas those in Europe often rely more on ultrasound evaluation. Regardless of the type of imaging, the follow-up regimen can be divided into three time segments:

- Early evaluation (first 4 months) to identify early ureteroileal anastomotic strictures caused by technical difficulties or poorly vascularized distal ureters.
- Middle period (4 months to 3 years) primarily focused on detecting cancer recurrence. This is best managed with CT or other cross-sectional imaging, which also allows evaluation of the upper tracts and reservoir for stones or obstruction. The frequency of the follow-up can be risk-adapted according to the pathologic findings at the time of cystectomy and the risk of subsequent recurrence.
- Long-term follow-up (beyond 3 years) to detect pouch stones, late upper tract obstruction, and urothelial carcinoma arising in the urethra or upper tracts.

BOX 99-1 Suggested Follow-up Protocol for Bladder Cancer Patients after Cystectomy and Orthotopic Diversion

EVERY 4 MONTHS FIRST YEAR, THEN EVERY 6 MONTHS TO 3 YEARS, THEN ANNUALLY

Physical examination including pelvic and rectal examination
Serum comprehensive metabolic panel, complete blood count

ANNUAL VISITS ONLY

Voided urine cytology
Urethral wash cytology (if carcinoma in situ on pathology)
Vitamin B₁₂ level
Prostate-specific antigen (if prostate cancer on pathology)

IMAGING DEPENDING ON CYSTECTOMY PATHOLOGY

Stage pT3 or N+ or higher: computed tomography (CT) of abdomen and pelvis with intravenous contrast, CT of chest or chest radiograph at each visit

Stage pT2 or lower: CT and chest radiograph at 4 and 12 months, then annually to 5 years, then every 2 years thereafter (may replace with ultrasonography after 3 years)

Our current follow-up scheme is shown in [Box 99-1](#), but others have been described ([Thurairaja and Studer, 2008](#); [Yafi et al, 2012](#)). We routinely perform digital rectal examination and cytology on both voided urine and in selected cases urethral wash in male patients, especially those with CIS in their primary pathology. It does require a cytologist with experience in looking at urine specimens from neobladder patients to be adept at evaluating them. Women should be evaluated with bimanual examination and voided cytology, because urethral recurrence will not be evident on CT scan. Cystoscopy should be performed in any patient who develops new-onset retention, a change in voiding pattern, or hematuria.

KEY POINTS: COMPLICATIONS FROM ORTHOTOPIC NEOBLADDERS AND RECOMMENDED FOLLOW-UP

- Early morbidity and mortality of cystectomy and orthotopic diversion are not increased compared with ileal conduit.
- Undrained urine leak is best managed using percutaneous drains and bilateral nephrostomy tubes when necessary. Early open surgical revision should be avoided.
- The majority of late urologic complications related to the neobladder can be managed using endoscopic techniques.
- Patients require regular follow-up imaging to identify upper tract obstruction and stones, which may be clinically silent.
- Follow-up should include rectal and pelvic examination and urethral cytology to identify urethral recurrence, which occurs in approximately 10% of males and rarely in females.

Quality of Life after Orthotopic Urinary Diversion

During the past two decades, there has been an increasing focus on quality-of-life issues and outcomes in various urologic diseases. This has been aided by the development of new, health-related quality-of-life instruments for use specifically in urology. Health-related quality of life can be defined as a patient's evaluation of the impact of a health condition and its treatment on relevant aspects of his or her life. Quality-of-life issues are becoming increasingly important in selection of the type of urinary diversion and are likely to play a larger role in future management of patients undergoing lower urinary tract reconstruction after cystectomy.

Initial studies in the 1980s pioneered comparative evaluation regarding quality-of-life issues in patients with different forms of urinary diversion after cystectomy. They demonstrated that, in general, patients were satisfied with their diversion and adapted reasonably well socially, physically, and psychologically. Boyd and colleagues studied patients with ileal conduit diversions compared with patients primarily with continent cutaneous diversion. Patients with an ileal conduit had the lowest expectations of that form of diversion but also had the poorest self-image, with a greater decrease in sexual desire and in all forms of physical contact (sexual and nonsexual) ([Boyd et al, 1987](#)). Mansson and colleagues demonstrated that urinary diversion affects most aspects of life in all patients. Although problems related to the diversion procedure tend to be fewer in patients with continent cutaneous reservoirs than in patients with ileal conduits, both forms of diversion could be associated with serious social, sexual, mental, and emotional problems ([Mansson et al, 1988](#)). This group also demonstrated the importance of how quality-of-life data are collected in terms of the results obtained ([Mansson et al, 2004](#)).

Hobisch and colleagues used both standardized and institutionally developed questionnaires to compare 69 patients with orthotopic diversion with 33 patients who underwent an ileal conduit. Patients with the continent diversion were more likely to recommend the procedure to friends, more likely to describe themselves as feeling "completely safe" with their diversion (74.6% vs. 33.3%), and more likely to feel "not handicapped at all" (92.8% vs. 66.7%). However, the ileal conduit patients were significantly older, more likely to be female and unmarried, and less likely to be working ([Hobisch et al, 2000](#)). All these factors can affect quality of life.

Bjerre and colleagues compared health-related quality of life in patients undergoing an orthotopic neobladder (38 patients) or an ileal conduit (29 patients) form of diversion. Despite higher daytime and nighttime urine leakage in the bladder substitute group, the urine leakage affected conduit patients more severely, and they scored higher on a leakage distress scale. The ileal conduit group was also found not to retain healthy body image as well as patients with a bladder substitute ([Bjerre et al, 1995](#)).

Hart and colleagues reported on a total of 221 patients (25 ileal conduit, 93 cutaneous Kock pouch, and 103 orthotopic neobladder) who completed four self-reported questionnaires including a profile of mood states and adapted versions of the sexual history form, body image dissatisfaction scale, and quality-of-life questionnaire. This study compared self-reports of emotional distress; global quality of life; sexuality; body image dissatisfaction; urinary diversion problems; and problems with social, physical, and functional activities. Regardless of the form of urinary diversion, the majority of patients reported good overall quality of life, little emotional distress, and few problems with social, physical, or functional activities. Problems with urinary diversion and sexual function were identified as most common. **After controlling for age, the researchers found no significant differences in any quality-of-life area among the urinary diversion subgroups** ([Hart et al, 1999](#)).

Weijerman and colleagues compared quality-of-life issues in patients undergoing either an orthotopic or a cutaneous continent urinary diversion. Quality-of-life assessment in this study revealed only a minor advantage for an orthotopic placement. It is important to note that quality-of-life assessment was found to be favorable for both types of urinary diversion ([Weijerman et al, 1998](#)). McGuire and colleagues used a well-validated survey to assess the impact of different forms of urinary diversion on overall quality of life in patients with locoregional bladder cancer after cystectomy. This study evaluated a total of 92 patients, including 38 with neobladder, 16 with Indiana pouch, and 38 with an ileal conduit. The mean physical scores were 48.4, 48.4, and 41.4 and mean mental scores were 51, 55.7, and 48.2 in the three groups, respectively. These results were not statistically different from one another or from published age-based and sex-based population norms, except for the mental score in the conduit group ([McGuire et al, 2000](#)). Autorino similarly used a validated tool for assessment of overall quality of life, the 36-Item Short Form Health Survey (SF-36), and found that the cystectomy patients scored worse than

the general Italian population in most domains but that there was no difference between the neobladder and conduit patients (Autorino et al, 2009).

There have been a number of efforts to develop a new tool that is more specific to patients with muscle-invasive bladder cancer. A few such validated questionnaires include the Functional Assessment of Cancer Therapy–Bladder (FACT-BL), the European Organisation for Research and Treatment of Cancer 30-item quality-of-life questionnaire for patients with muscle-invasive bladder cancer (EORTC QLQ-BLM30), the BCI, and the Vanderbilt Cystectomy Index (FACT-VCI) (Cookson et al, 2003; Gilbert et al, 2007). Each has its advantages and disadvantages, especially when applied to a specific group of patients. Large and colleagues used the FACT-VCI to compare 45 women who underwent an Indiana pouch procedure with 47 who underwent a neobladder construction and found no significant differences between the two groups on any of the quality-of-life domains (Large et al, 2010). Gilbert and colleagues validated and used the BCI and found that neobladder patients scored significantly worse on that index, influenced largely by a higher rate of urinary leakage and dribbling for the neobladder patients than for the conduit patients (on these measures the conduit patients scored better than untreated bladder cancer patients with their native bladder) (Gilbert et al, 2007).

Most of the studies that have evaluated and compared quality-of-life issues in patients undergoing various forms of urinary diversion have been criticized for methodologic problems that limit their conclusions (Gerharz et al, 2005; Porter et al, 2005; Gerharz, 2007). Critical analyses of the current quality-of-life literature suggest that there is not enough evidence to conclude that there is a clear quality-of-life advantage for patients undergoing continent diversion. Porter and Penson performed a systematic review to determine if any differences exist in health-related quality-of-life outcomes among different types of urinary diversion after radical cystectomy. Of 378 initial articles, only 15 studies met all their inclusion criteria. None of the studies were randomized trials, and only one was prospective. **Common limitations included unvalidated health-related quality-of-life outcome instruments, use of general health-related quality-of-life outcome instruments only, lack of baseline data, cross-sectional analysis, and retrospective study design.** The authors found that the current body of published literature is insufficient for it to be concluded that any form of urinary diversion is superior to another on the basis of health-related quality-of-life outcomes (Porter and Penson, 2005). Gerharz came to similar conclusions (Gerharz et al, 2005; Gerharz, 2007). Clearly, to better understand and evaluate these quality-of-life issues in patients undergoing various forms of urinary diversion, future studies in this area must incorporate prospective data collection, provide longer-term follow-up, and incorporate validated disease-specific health-related quality-of-life outcome instruments. With all instruments, the functional outcomes of different diversions and quality of life remain very difficult to assess, and it is extremely difficult to develop a single instrument that allows detailed comparison among different types of diversions.

In summary, there are not clear data showing an overall quality-of-life advantage for patients undergoing neobladder reconstruction, and most patients will clearly adapt to whatever specific challenges their urinary diversion presents to them. Nevertheless, when presented with the option, most patients will choose orthotopic diversion simply because it seems the most natural and avoids a permanent stoma, and having this option may encourage patients to more readily undergo definitive treatment of their bladder cancer. Patients must, however, have realistic expectations about the risk of incontinence and the possible need for self-catheterization.

KEY POINTS: QUALITY OF LIFE AFTER URINARY DIVERSION

- Most quality-of-life studies that have evaluated and compared patients undergoing various forms of urinary diversion have been criticized for methodologic problems that limit their conclusions.
- The current body of published literature is insufficient to conclude that any form of urinary diversion is superior to another on the basis of health-related quality of life outcomes.

Intracorporeal versus Extracorporeal Diversion

Future Direction

The conventional laparoscopic approach to intracorporeal urinary diversion has evolved since 1992 and its adaption was hindered by prolonged operative times, limitations of instrument maneuverability, and a steep learning curve (K.O., 1992; Sanchez de Badajoz et al, 1992; Potter et al, 2000). The compromise resulting from these difficulties led to hybrid procedures in which extirpation and lymph node dissection were performed by conventional laparoscopy and diversion was completed using a modified open approach (Haber et al, 2007).

The robot-assisted surgical approach for pelvic urologic oncology has existed since the mid-2000s (Menon et al, 2003; Guru et al, 2008), and the technique for robot-assisted radical cystectomy (RARC) with lymph node dissection has been established (Poch et al, 2013). Early oncologic outcomes after RARC and lymph node dissection are safe and efficacious (Hellenthal et al, 2010, 2011). Several perceived advantages of robot-assisted approaches for bladder cancer include less pain, minimal blood loss, and earlier return of bowel function, which ultimately help in a quicker return to previous quality of life (Challacombe et al, 2011). Despite smaller incisions and advances in extirpation, recovery has relied mainly on return of bowel function (Johar et al, 2013). More than 1700 cases of RARC have been registered in the International Robotic Cystectomy Consortium database (IRCC)—a quality assurance conglomerate of 58 surgeons at 33 institutions in 11 countries. Based on data published in 2013 from the IRCC, approximately 18% of procedures have been performed with the complete intracorporeal approach (Ahmed et al, 2014). Two commonly performed procedures with the complete intracorporeal approach include the ileal conduit and a modified Studer neobladder.

PATIENT SELECTION

One of the contraindications for the minimally invasive approach is decreased pulmonary compliance resulting from the inability to tolerate the steep Trendelenburg position, especially with prolonged operative duration during intracorporeal diversion. Use of ileum is contraindicated in patients with short bowel disease, severe inflammatory bowel disease, and changes related to extensive

KEY POINTS: INTRODUCTION

- A steep learning curve, prolonged operative times, and limitations of instrument maneuverability have hindered progress in minimally invasive urinary diversion with conventional laparoscopy.
- Advantages of robot-assisted approaches for bladder cancer possibly include less pain, minimal blood loss, and earlier return of bowel function.
- Approximately 18% of RARCs have been performed with the complete intracorporeal approach.

radiation. Absolute and relative contraindications for neobladder are similar to open surgery. The absolute contraindications include involvement of the urethra distal to the prostate, inadequate renal (serum creatinine >2 mg/dL), and poor hepatic function (Parekh and Donat, 2007).

PREOPERATIVE CARE

A clear-liquid diet 12 hours before surgery has become the standard; meanwhile, solid diet intake has been allowed up to 6 hours before surgery (Smith et al, 2011). Mechanical bowel preparation with oral antibiotics preoperatively is avoided. Bowel preparation can lead to electrolyte imbalance especially in elderly patients, and in some cases intracorporeal opening of bowel may lead to spillage of liquid content, which is annoying and can also become a source of infection. Several studies have shown no advantage to oral mechanical bowel preparation before surgery (Cerantola et al, 2013).

Intermittent pneumatic compression and leg stockings are recommended. To avoid significant cardiovascular complications (≤5%), anticoagulant treatment is recommended with low-molecular-weight heparin based on the body weight before and up to 4 weeks after surgery (Johar et al, 2013). Broad-spectrum intravenous antibiotics are preferably administered up to 1 hour before the start of the procedure.

KEY POINTS: PATIENT SELECTION AND PREOPERATIVE CARE

- Decreased pulmonary compliance is a **contraindication** for the minimally invasive approach.
- **Absolute contraindications** for the neobladder are same as for open surgery.
- Mechanical bowel preparation should be avoided.
- Anticoagulant treatment can help avoid significant cardiovascular complications ($\leq 5\%$).
- Preoperative broad-spectrum intravenous antibiotics are preferably given **up to 1 hour** before the start of the procedure.

PATIENT POSITION AND PORT PLACEMENT

After the induction of general endotracheal anesthesia, a nasogastric tube and a Foley urinary catheter are inserted. The patient is placed in lithotomy position with arms adducted and padded. The legs are also abducted and slightly lowered on spreader bars or stirrups. The patient is positioned in a steep Trendelenburg position and the abdomen is insufflated with a Veress needle or the Hasson technique. A **six-port transperitoneal approach** is used and all the ports after the camera port are placed under direct vision and more cephalad. This positioning of the ports helps in small-bowel maneuvering during urinary diversion and extended lymph node dissection along the aortic bifurcation. In the six-port configuration, the camera port is placed above the umbilicus (midline or on the left side). Two robotic ports are placed symmetrically at the level of or just below the umbilicus on the left and right sides, lateral to the rectus sheath. While performing the neobladder procedure, the third (right-assistant) and fourth (left-side) ports (12 to 15 mm) are placed just above and medial to the anterior superior iliac spines. The robotic arm could be used alternatively with an assistant instrument or by inserting an additional

robotic arm inside the 15-mm laparoscopic port for stapling during neobladder creation. A 5-mm (12-mm for neobladder) port is placed between the camera and the right robotic arm port. An extra short 12-mm port is inserted in the suprapubic area for bowel reanastomosis while performing the marionette ileal conduit. This port helps in aligning the bowel during reanastomosis and can be extended and converted to a Pfannenstiel incision for specimen removal in male patients.

A 0-degree lens is used during this procedure. Occasionally it is advantageous to use a 30-degree down lens for a deep female pelvis during extended lymph node and vascular pedicle dissection. The use of a “**technique of spaces**” is important in completing extirpation of the bladder and adjacent organs; the division of the procedure into well-defined steps facilitates teaching and keeps the procedure focused. The **four spaces** of dissection are **periureteral, lateral pelvic, anterior rectal, and retropubic space** (Poch et al, 2013). Extended lymph node dissection is performed up to the aortic bifurcation, which helps with the crossing of the left ureter to the right side for the urinary diversion. After the bladder with adjacent organs and the lymph nodes are placed in the specimen bags and transferred to the pelvis, attention is directed toward the intracorporeal ileal urinary diversion. **Before embarking on intracorporeal neobladder, the robotic arms are dedocked from the ports and the steep Trendelenburg position is reduced to 10 degrees to 15 degrees** for ease of urethra-neobladder anastomosis. Tables 100-1 and 100-2 summarize the steps and instruments used in the creation of robot-assisted intracorporeal ileal conduit and neobladder, respectively.

CREATION OF ILEAL CONDUIT

Transfer of Left Ureter and Selection of Bowel

The left ureter is crossed underneath the sigmoid colon and over the great vessels to the right side. It is important to identify patients with duplication of ureters, so that they can be implanted separately or together, depending on the caliber of the ureter. **If the length of the left ureter is short, the sigmoid is retracted with the fourth arm; occasionally a 30-degree down lens helps to identify and**

KEY POINTS: PATIENT POSITION AND PORT PLACEMENT

- Intracorporeal diversion is performed with a six-port transperitoneal approach.
- All of the ports are placed more cephalad to help in the maneuvering of the bowel.
- For the neobladder, a 15-mm laparoscopic port can be used alternatively with an assistant instrument or by inserting an additional robotic arm.
- A 0-degree lens is used during intracorporeal urinary diversion.
- The “technique of spaces” is used for the extirpation of the bladder, which divides the entire procedure into well-defined steps to facilitate teaching and to keep the procedure focused.
- Before the intracorporeal neobladder creation, the robot should be undocked and the steep Trendelenburg position should be reduced to facilitate urethra-neobladder anastomosis.

free the proximal left ureter. A 12-cm long segment of ileum is identified (15 to 20 cm proximal to the ileocecal valve). Adequate bowel length on the ileocecal end of the bowel should be left in place to avoid kinking after the conduit is exteriorized and repositioned.

The Marionette Stitch

A 60-inch 1-0 silk suture using a Keith needle is introduced via the hypogastrium of the anterior abdominal wall and is passed through the distal end of the bowel segment (future stoma), then it is brought back through the same location on the anterior abdominal wall (Fig. 100-1). The marionette stitch is held together using a surgical instrument; not tying the marionette stitch allows free movement of the bowel segment during the creation of the conduit. The marionette stitch manipulates the bowel segment to

Figure 100-1. Keith needle used to transfer marionette stitch (placed into the stomal [distal] end of ileal conduit) out to the exterior for clamping.

adjust for the limitation of fixed ports and it enables mobilization of different areas of the conduit into the surgical field. The marionette stitch is especially helpful in patients with a limited distance between physical boundaries of the abdomen/pelvis and the true operative space. The marionette stitch can be placed further down in the pelvis to keep the operative field in range of optimal mechanical joint movements of the robotic instruments.

Isolation of the Bowel Segment and Creation of the Ileal Conduit

The fourth arm is used to hold the proximal segment of the bowel at stretch opposite to the stoma end (held by the marionette stitch); meanwhile the hook cautery is used to incise the peritoneum of the bowel mesentery. It is important to keep the appropriate orientation of the bowel and to avoid mesenteric narrowing of the base of the conduit (which limits mesenteric blood supply). Another alternative is to use a vascular stapler across the mesentery, which makes this process quicker. After the two mesenteric windows are created

(Fig. 100-2), a 45-mm Endo GIA stapler is used to divide the bowel proximally and distally (Fig. 100-3). The incised ends are held together using a 0-silk suture to avoid malrotation during anastomosis. The bowel reanastomosis is not established at this point. In our experience, ileal conduit segment washout has been abandoned, as it does not impact infection and avoids spillage during stent manipulation and ureteroileal anastomosis.

Ureteroileal Anastomosis

Two openings are created on either side of the proximal end of the conduit using either scissors or an electrocautery hook (Fig. 100-4).

After the marionette is lowered, the ureter is implanted with minimal traction and stretching of the proximal end of the ileal conduit. After the efflux of clear urine is seen, the spatulation is performed for wide anastomosis with ease. The fourth arm is used to retract the cut end of the distal ureter, and spatulation of the proximal ureter is performed (Fig. 100-5). We prefer to implant the left ureter first for ease of anastomosis.

The two commonly used techniques of anastomosis include Bricker and Wallace. A Bricker anastomosis is a refluxing end-to-side anastomosis and is easy to perform while keeping the two renal units separate. Meanwhile the Wallace technique joins the ends of the two ureters in a Y fashion, anastomosing a single limb to the proximal portion of the ileal conduit (Rehman et al, 2011).

A few key issues should be remembered while performing this anastomosis. The position in which the anastomosis is carried out is not the final position in which the proximal end of the conduit will lie. The trick is to place the initial suture in the conduit opening first (outside in) and then into the angle of the incision in the ureter (inside out). The suture on the conduit side should be perpendicular to the proximal staple line of the conduit. This helps to align the ureter and avoids back-walling of the ureter. This initial suture sets the stage for a proper alignment and placement of the subsequent sutures. Interrupted sutures can also be run along both sides halfway up to the middle of the anastomosis, after which the stent is placed. Van Velthoven-type, double-armed, 4-0 Vicryl sutures approximately 5-cm long can also be used to suture the angle of the spatulation and can continue along both sides (Fig. 100-6). After completion of anastomosis of the posterior wall, the ureteral stent is introduced. A metal laparoscopic suction tube is passed into the distal conduit through the 15-mm right

Figure 100-7. Metal suction tip held in place with robotic arm to insert single J stent across the anastomosis.

assistant port. The metal laparoscopic suction tube is pushed gently across the conduit and positioned at the junction of the conduit and the ureteric anastomosis. The metal suction tip is held in place by the robotic needle driver to allow passage of a stent through it without damaging the anastomosis (Fig. 100-7). This maneuver helps to facilitate threading of the 90-cm, 8.5-Fr, single-J ureteral stent with a guidewire into the renal pelvis. The guidewire is kept in the stent until it is secured to the conduit using 3-0 chromic stitches to prevent accidental dislodgment of the stent. The guidewire is removed only after the suture is placed, as it is difficult to identify the stent because of a lack of tactile feedback. The distal end of the ureter is excised completely and sent for final histopathology. The ureteroileal anastomosis is then completed. The distal ends (external portion) of both ureteric stents are left draining through the 15-mm side port. The exterior portions of the stents should not be clamped to the drape, which avoids accidental dislodgment during in vivo manipulation of the ileal conduit.

After the left side is anastomosed, the marionette is manipulated to turn the conduit on the other side and the right ureteric anastomosis is performed in a similar fashion.

Restoration of the Bowel

The two cut ends of small bowel are held in place by a stay silk suture. We prefer to reanastomose the bowel after the two ureters are anastomosed. This helps ease conduit manipulation and helps tailor the bowel reanastomosis to avoid kinking or tension. A new suprapubic port is inserted for ease of alignment of bowel reanastomosis. A 60-mm Endo GIA stapler is inserted through the short 12-mm suprapubic port. An end-to-end anastomosis is performed after both ends of the bowel are aligned along their antimesenteric borders (Fig. 100-8). The open ends of the two anastomosed intestinal segments are stapled by firing an Endo GIA stapler horizontally via the right assistant port (Fig. 100-9). A secure stay suture is placed to reduce tension and to support the edge of the antimesenteric border. The mesentery window is closed using a 3-0 silk suture.

Prestoma Preparation

The robot is left docked and the instruments are removed. The surgeons scrub to create the stoma opening by making a cruciate incision in the anterior fascia and inserting the four stay sutures to anchor the conduit after it is externalized. After completion of four fascial sutures, the robotic arms are reinserted. The pelvis is exam-

Figure 100-8. Extra short suprapubic (12 mm) port inserted for side-to-side bowel anastomosis held in place with graspers.

Figure 100-9. Alignment for transverse closure of bowel anastomosis performed via the right assistant port.

ined for any bleeding, and strings of all specimen bags are removed via the suprapubic port. A vascular clamp is introduced via the stoma opening under direct vision into the abdominal cavity to remove the marionette suture and the free ends of the ureteric stents. A Jackson-Pratt drain is introduced via the right assistant port and the robot is dedocked after the robotic instruments have been removed. Finally the distal end of the conduit is brought out gently through the stoma site, assuring proper orientation after the pneumoperitoneum is lowered.

KEY POINTS: CREATION OF ILEAL CONDUIT

- To avoid kinking of the conduit when it is exteriorized and repositioned, adequate length of the bowel at the ileocecal junction should be retained.
- The marionette stitch is not tied to allow free movement of the bowel segment during the creation of the conduit.
- As the ileal conduit segment washout does not impact infection and causes more spillage, it has been abandoned.
- The ureteral stent guidewire is removed only after the tagging suture is placed, as the lack of tactile feedback makes it difficult to identify the stent.
- The exterior portions of the ureteral stents should not be clamped so as to avoid accidental dislodgment.

Figure 100-10. Tension-free ileum to urethra anastomosis is the first step of the intracorporeal neobladder creation. (Courtesy Professor Peter Wiklund, MD, PhD.)

Figure 100-11. Reconfiguring and creation of posterior plate of neobladder. (Courtesy Professor Peter Wiklund, MD, PhD.)

CREATION OF MODIFIED STUDER NEOBLADDER

The small bowel is assessed for its tension-free ease of approximation to the urethral stump with minimal traction. The significant difference between various approaches is the performance of early enterourethral anastomosis advocated by the Karolinska group. The alternate approach uses the fourth arm to hold traction at the future urethral anastomosis site in the small bowel and to perform anastomosis after the posterior plate of the neobladder is constructed.

Neobladder-Urethral Anastomosis

The ileum is sufficiently mobilized to perform a tension-free neobladder-urethral anastomosis. Using robotic scissors, an opening is made at the most dependent, tension-free antimesenteric portion of the ileum. The anastomosis is performed by the Van Velthoven technique with a 4-0 Quill suture (Fig. 100-10). Some anecdotal experiences have suggested that the V-Loc suture (Covidien, Minneapolis, MN) should not be used because of the sharper and larger barbs that may traumatize the neobladder. In situations where it is difficult to approximate the bowel to the urethra easily, the neobladder is held in position between two customized Penrose drains rolled around the intestine (urethral end of the future neobladder). A silicone catheter is used to identify easily the urethral stump, similar to urethrovesical anastomosis during robot-assisted radical prostatectomy.

Various maneuvers are advocated if it is difficult for the ileum to reach the urethra: reducing Trendelenburg positioning, using the Penrose drain for gentle stretching and traction, releasing and incising the peritoneum over the mesentery, stapling the medial/proximal portion of the mesentery (care is needed to avoid risking ischemia to the isolated bowel segment), and, finally, dissecting the ileum around the ileocecal region.

Isolation of Bowel

The orthotopic neobladder is tailored based on the Studer principles using a 40-cm segment of terminal ileum for the body of the neobladder and approximately 10 to 15 cm for the afferent limb. The intestine is isolated using a laparoscopic 60-mm bowel stapler. The bedside assistant can use the hybrid 15-mm port to insert the stapler for ease of alignment with the bowel. The ileum is stapled 40 cm proximal to the ureteroileal anastomosis. Integrity of small bowel is usually restored using staplers; however hand-sewn anastomosis has also been reported as safe. The stapler-based reanastomosis is performed based on a side-to-side method.

Detubularization of Bowel

The distal 40 cm of the isolated ileal segment is detubularized along the antimesenteric border with cold scissors or by inserting

Figure 100-12. Two sides of ureters are configured using a running suture after the edges are aligned and held in place. (Courtesy Professor Peter Wiklund, MD, PhD.)

a 24-Fr chest tube for ease of identification of the most antimesenteric portion. A 10-cm proximal isoperistaltic afferent limb is left intact to anastomose the ureters.

Modified Studer Neobladder

The posterior part of the Studer neobladder is closed using absorbable running sutures (2-0 or 3-0 V-Loc). A 0-degree or 30-degree down lens can be used for this portion of the procedure (Fig. 100-11). After the posterior part is sutured, the distal half of the anterior part of the reservoir is also sutured in a similar fashion. The anterior part of the reservoir is not sutured completely and is closed toward the end of the procedure. The USC group advocates 90-degree counterclockwise rotation of the pouch at this stage.

Uretero-Neobladder Anastomosis

The Bricker anastomosis is performed between the ureters and the afferent limb. A 4-0 Vicryl or a 3-0 Biosyn suture is used for anastomosis. The left ureter is transposed to the right side by creating a tunnel under the sigmoid mesentery. During the Wallace anastomosis the ureters are spatulated and joined at the posterior walls of the ureters. The Wallace plate is sutured to the afferent limb of the Studer reservoir, using a 4-0 Vicryl or a Quill suture (Fig. 100-12). Two single-J 40-cm ureteric stents are introduced before closing the ureters (Fig. 100-13). The stents are passed through the afferent limb and mobilized up to the ureters. The stents can be brought out via the midline just above the pubic symphysis or internalized by using double J stents.

Two ureters are arranged in Wallace fashion to anastomose with proximal end of Studer neobladder

Figure 100-13. Anastomosis is performed and helps align right and left ureter to create Wallace plate. (Courtesy Professor Peter Wiklund, MD, PhD.)

Closure of the Neobladder

The remaining part of the reservoir is closed toward the completion of the neobladder. The balloon of the indwelling catheter is filled with 10 cc of water. The neobladder is checked for any anastomotic leakage. A Jackson-Pratt drain is placed in the pelvis away from the urethra-neobladder anastomosis.

KEY POINTS: CREATION OF MODIFIED STUDER NEOBLADDER

- The significant difference among various approaches at neobladder formation is in initially performing the enterourethral anastomosis.
- The bowel can be mobilized to the urethra by holding the neobladder in position between two customized Penrose drains rolled around the intestine.
- Maneuvers to help the ileum reach the urethra include:
 - reducing Trendelenburg position.
 - using the Penrose drain to hold the ileum.
 - incising and releasing the peritoneum over the mesentery.
 - stapling the medial/proximal portion of the mesentery.
 - dissecting the ileum around the ileocecal region.
- Use of the hybrid 15-mm port by the bedside assistant can help ease alignment of the stapler with the bowel.
- The anterior part of the reservoir is closed toward the end of the procedure.

POSTOPERATIVE CARE

Optimizing fluid balance and avoiding overhydration should help manage fluid shift in this patient population with advanced age. Cochrane meta-analysis showed no advantage to leaving the nasogastric tube after surgery (Nelson et al, 2007). Pelvic drainage is preferred; we use both a drain as well as the Foley via the urethra as a drain (removed postoperative day 1 in ileal conduits). Adequate pelvic drainage and stenting of ureters, especially at the anastomosis, have already proven helpful in healing and reduction of metabolic acidosis, possibly because of minimal reabsorption. Drains can usually be removed at discharge. The ureteral stents if exteriorized to skin are removed a week after surgery. If the stents are internalized, removal of the double J stents is recommended with cystoscopy when the neobladder has healed at 3 to 4 weeks. The urethral catheter can be removed approximately 3 to 4 weeks postoperatively after the absence of any leak is confirmed on pouchography. Irrigation of the neobladder is recommended every 8 hours to avoid mucus plugging and catheter blockage.

Enhanced Recovery after Surgery

Multimodal perioperative pathway, especially enhanced recovery after surgery (ERAS), has recently evolved with more than 20 key components and has been tailored by several cystectomy experts (Karl et al, 2014; Patel et al, 2014; Xu et al, 2015). Recent modifications include early use of alvimopan, intraoperative goal-oriented fluid optimization, immediate initiation of oral diet, and reduced narcotic use. Xu and colleagues (2015) compared traditional pathway to an enhanced recovery protocol and reported decreased opioid usage per day, incidence of ileus, and hospital stay; however, they reported more pain. Opioid use for breakthrough pain underwent a radical change from opioid PCA (patient-controlled analgesia) and epidurals to high-dose acetaminophen and/or ketorolac.

KEY POINTS: POSTOPERATIVE CARE

- In patients with advanced age, optimization of fluid balance and avoidance of overhydration helps to manage fluid shifts and to control complications.
- Pelvic drainage and stenting of ureters help in bowel recovery and reduce metabolic acidosis.
- The neobladder irrigation is recommended every 8 hours to avoid mucus plugging and catheter blockage.

OUTCOMES

Intracorporeal urinary diversion attempts to minimize bowel manipulation and to reduce postoperative pain with minimal wound retraction and smaller incisions. The first published report of robot-assisted intracorporeal neobladder appeared in 2003 (Beecken et al, 2003). Several factors have facilitated performance of the procedure with an intracorporeal technique. First, RARC and the extended pelvic lymph node dissection technique have been standardized with oncologic results equivalent to standard open techniques (Raza et al, 2015). Second, the understanding of the robot-assisted surgical platform along with improving console-based surgical skills have allowed the robotic surgeons to optimize the use of this technology. The advantage of the EndoWrist technology in robot-assisted surgery allows surgeons to use the mechanical wrist for suturing and reconstructive purposes with minimal effort in comparison to conventional laparoscopy. This section addresses various key factors that define the acceptance of intracorporeal urinary diversion based on operative technique, learning curve, hospital stay, complications, functional outcomes, and comparison between intra- and extracorporeal outcomes.

OPERATIVE TECHNIQUE

One of the major limitations of incorporating intracorporeal diversion has been prolonged operative time (Balaji et al, 2004; Hubert et al, 2006). Initial reports of operative times up to 450 minutes made this approach unacceptable, as the patient population is at risk because of age and comorbidity. More recent literature shows that overall operative times have been reduced (almost equivalent to the open approach), and the technique is standardized. Open conversion is rare, with only two technique-related reports (Table 100-3).

In one of the largest reported series of 100 consecutive robot-assisted intracorporeal ileal conduits, median overall operative time was 352 minutes with an estimated blood loss of 300 mL and no conversion (Azzouni et al, 2013). In a separate combined series of 36 intracorporeal neobladders and 9 ileal conduits, Jonsson and coworkers (2011) reported an acceptable median operative time (460 minutes for ileal conduits and 480 minutes for neobladders).

TABLE 100-3 Comparisons of Operative Parameters for Robot-Assisted Intracorporeal Urinary Diversion

SERIES (YEAR)	PATIENTS	DIVERSION	OVERALL OPERATIVE TIME (min)	DIVERSION TIME (min)	CONVERSION TO OPEN	INTRAOPERATIVE DIFFICULTY/ COMPLICATIONS
Goh et al (2012)	15	Ileal conduit 7 Neobladder 8	450	NR	0	0
Azzouni et al (2013)	100	Ileal conduit	352	123	0	0
Canda et al (2012)	25	Ileal conduit 2 Neobladder 23	624	NR	1	Inability to anastomose

NR, not reported.

with no conversion. Pruthi and colleagues (2010) in their early series (3 neobladders and 9 ileal conduits) had an excellent mean operative time of 318 minutes. The quicker operative times reported by this group are possibly attributed to the U configuration and the use of absorbable staplers for configuring the neobladder. Rehman and coworkers (2011) in a series of 9 ileal conduits reported a mean operative time of 346 minutes and described one postoperative patient with iatrogenic necrosis of the ileal conduit, which was revised and was possibly related to an initial experience with the intracorporeal approach. The key issue during the early experience is maintaining orientation during and at the completion, as no opportunity exists to correct orientation after the ports are removed and the stoma is retrieved. Goh and colleagues (2012) in their initial experience of seven ileal conduits reported a median operative time of 450 minutes, which was consistent with the early adaption of the intracorporeal approach.

LEARNING CURVE

Collins and coworkers (2014) evaluated the learning curve of intracorporeal neobladders and found that overall operative times and the risk of conversion were reduced from 30% to 10% after only 10 consecutive procedures. A reduction in complications was observed in both early (70% to 30%) ($P < .05$) and late (50% to 0%) ($P = .011$) categories as the surgeons gained experience with intracorporeal neobladder. The mentoring effect was helpful in reducing overall operative time, and it helped avoid open conversion during early experiences. Conversion of intracorporeal neobladder to open was associated with an increase in overall length of stay.

HOSPITAL STAY

The literature does not show evidence of significant reduction in hospital stay except for the University of North Carolina series that showed a reduced average stay of 4.5 days (Pruthi et al, 2010). In the IRCC comparative study (Ahmed et al, 2014) median hospital stay was marginally longer with intracorporeal urinary diversion (9 days vs. 8 days, $P = .086$).

COMPLICATIONS

It is difficult to attribute all reported complications to urinary diversion, as the patients also underwent radical cystectomy and a lymph node dissection, which can be morbid and responsible for a portion of reported complications. The possible attributed advantages in terms of reduced bowel manipulation, decreased insensible losses, and minimal need for analgesia can possibly help reduce the significant morbidity of this procedure.

Based on literature (only describing case series >10) overall early (30-day) and late (90-day) complications were up to 73% and 81%, respectively (Table 100-4). High-grade complications were observed in up to 37%, and sepsis was the most common cause of these complications. The reoperation rate at 30 days was as high as 17%; meanwhile the readmission rate ranged between 22% and 60%.

FUNCTIONAL OUTCOMES

The most significant functional outcomes related to the neobladder are return of continence and sexual function. Canda and colleagues (2012) evaluated 23 patients who underwent intracorporeal Studer neobladder and found that 61% were fully continent and 22% experienced mild daytime incontinence. Erectile function was evaluated based on the International Index of Erectile Function scores with poor return of results attributed to limited follow-up and decreased libido. Goh and coworkers (2012) at 3-month follow-up had complete return of daytime continence in six patients and only one patient required conversion to a continent cutaneous pouch. Tyritzis and colleagues (2013) showed that 74% of men and 67% of women were continent (either no or one pad per day). A total of 81% of patients who underwent a nerve-sparing procedure were potent with or without oral medications at 12 months. A total of 67% of females also remained sexually active after surgery.

INTRACORPOREAL VERSUS EXTRACORPOREAL DIVERSION

The IRCC compared outcomes (935 patients) between intracorporeal (167 patients, including 106 ileal conduits and 61 neobladders)

TABLE 100-4 Comparisons of Clinical Outcomes following Robot-Assisted Intracorporeal Urinary Diversion

AUTHOR (YEAR)	TYPE/NUMBER	COMPLICATIONS (%) (30 DAYS, 90 DAYS)	MOST COMMON COMPLICATION	HIGH-GRADE COMPLICATION (%)	REOPERATION (%) (30 DAYS)	READMISSION (%) (90 DAYS)	MORTALITY (%) (90 DAYS)

NR, not reported.

(18%) and extracorporeal urinary diversion (Ahmed et al, 2014). Only eight of 18 institutions had performed intracorporeal urinary diversion, and in 55% of these eight centers the intracorporeal approach was performed with a volume of less than 100 robot-assisted radical cystectomies per year. Operative times were comparable, suggesting experienced robotic surgeons were engaged in advanced reconstructive robot-assisted surgery. A total of 35% of intracorporeal and 43% of extracorporeal urinary diversions presented with a complication within 30 days of surgery. **Readmission rates at both 30-day (5% vs. 15%, $P \leq .0001$) and 90-day (12% vs. 19%, $P = .011$) were lower in the intracorporeal group. Blood transfusions were significantly lower in the intracorporeal group (7% vs. 16%, $P = .022$). Gastrointestinal-related complications were significantly lower in the intracorporeal group (10% vs. 23%, $P \leq .001$), supporting the notion that minimal bowel manipulation and open bowel exposure may help in lowering complications and might possibly help with early recovery. In the intracorporeal group, 90-day mortality was lower (1.6% vs. 4.9%, $P = .043$), which may be explained based on patient selection and experience of the robotic surgeon until randomized controlled studies clearly show a difference. The number of patients returning to the operating room was higher in the intracorporeal group (8% vs. 6%, $P = .421$).**

KEY POINTS: OUTCOMES

- Prolonged operative time has limited the incorporation of intracorporeal diversions.
- It is critical to maintain proper orientation of the bowel and the conduit during and at the completion of the procedure, as no opportunity exists to correct orientation after the ports are removed and the stoma is retrieved.
- Mentoring is helpful in reducing overall operative time and open conversions during early experience.
- Sepsis is the most common cause of complications following intracorporeal urinary diversion.
- Return of continence and return of sexual function remain the most significant functional outcomes related to the intracorporeal neobladder.
- Readmission rates, blood transfusions, and gastrointestinal-related complications are significantly lower in the intracorporeal group.
- Reoperation rates are noted to be higher in the intracorporeal group.

FUTURE DIRECTION

After the safe inclusion of RARC and lymph node dissection in our armamentarium, urinary diversion is now being performed worldwide. The biggest technical challenges of pelvic reconstruction with conventional laparoscopy have been suturing and the ability to maneuver in narrow spaces. The depth of image with three-dimensional magnification and the ability of the EndoWrist to assist with intracorporeal suturing using the surgical robot have made intracorporeal urinary diversion possible in a safe and time-sensitive fashion.

Randomized controlled trials are ideal for safety and functional outcomes; they are meanwhile supplemented, however, with standardized registry-based outcomes. A permanent place for intracorporeal urinary diversion in urologic surgery will depend not only on optimal operative times but also on a reduction in morbidity and a quicker return of quality of life. These parameters have to be properly measured and must demonstrate improvement in comparison to the standards set with open urinary diversion.

Injuries of the External Genitalia

Bladder Injuries

Urethral Injuries

The lower urinary tract may sustain injury through a wide variety of mechanisms. Although rarely life-threatening, mismanagement of these injuries can lead to considerable long-term morbidity. Optimal outcomes can be achieved by employing appropriate imaging and identifying the best timing and approach for intervention.

In the acute setting, it is important to distinguish between scenarios when immediate reconstruction is appropriate, such as testicular rupture, and when reconstruction is best delayed, such as pelvic fracture urethral injury. Appropriate management at the time of injury also facilitates delayed reconstruction—placement of a large-bore suprapubic tube at the midline for urethral injury makes delayed posterior urethroplasty easier to perform.

Improved technology and wider availability have made imaging more useful in lower urinary tract trauma, allowing for prompt and accurate diagnosis of injury. Better localization of the site of injury also allows the surgeon to select more direct or minimally invasive approaches for repair. Ultrasonography is routinely performed for scrotal trauma and is being performed more widely for diagnosis of penile fracture. Penile fracture localized to the ventral surface of the corpora can be repaired via a penoscrotal incision with excellent exposure. High-resolution computed tomography (CT) cystography can pinpoint the site of bladder rupture, making laparoscopic repair an excellent option. Retrograde urethrography can diagnose pelvic fracture urethral injury and differentiate between injuries where primary realignment is feasible and where suprapubic tube placement is the better alternative.

INJURIES OF THE EXTERNAL GENITALIA

Penis

Traumatic injuries to the genitalia are uncommon, in part because of the mobility of the penis and scrotum. Blunt phallic traumatic injury is usually of concern only with an erect penis, when fracture of the tunica albuginea may result. In general, prompt surgical reconstruction of most penile injuries usually leads to adequate and acceptable cosmetic and functional results.

Fracture

Etiology. Penile fracture is the disruption of the tunica albuginea with rupture of the corpus cavernosum. Fracture typically occurs during vigorous sexual intercourse, when the rigid penis slips out of the vagina and strikes the perineum or pubic bone, producing a buckling injury.

The tunica albuginea is a bilaminar structure (inner circular, outer longitudinal) composed of collagen and elastin. The outer layer determines the strength and thickness of the tunica, which

varies in different locations along the shaft and is thinnest ventrolaterally (Hsu et al, 1994; Brock et al, 1997). The tensile strength of the tunica albuginea is remarkable, resisting rupture until intracavernous pressures increase to more than 1500 mm Hg (Bitsch et al, 1990). When the erect penis bends abnormally, the abrupt increase in intracavernosal pressure exceeds the tensile strength of the tunica albuginea, and a transverse laceration of the proximal shaft usually results.

Although penile fracture has been reported most commonly with sexual intercourse, it also has been described with masturbation, rolling over or falling onto the erect penis, and other scenarios (Al Ansari et al, 2013). Penile fracture may occur more frequently in “stressful situations” such as extramarital sex (Kramer, 2011). In the Middle East, self-inflicted fractures predominate owing to the practice of taqaandan, in which the erect penis is forcibly bent during masturbation or as a means to achieve rapid detumescence (Zargooshi, 2009).

Mydlo (2001) reported that 94% of fractures in Philadelphia, Pennsylvania, were a result of sexual intercourse; Zargooshi (2009) described 76% of fractures in Kermanshah, Iran, as being due to self-manipulation. The tunical tear is usually transverse and 1 to 2 cm in length (Asgari et al, 1996; Mydlo, 2001). The injury is usually unilateral, although tears in both corporeal bodies occur in 10% of injuries (Mydlo, 2001; El-Taheer et al, 2004). Bilateral corporeal injuries are more commonly associated with urethral injury (Koifman et al, 2010). Although the site of rupture can occur anywhere along the penile shaft, most fractures are distal to the suspensory ligament. Injuries associated with coitus are usually ventral or lateral (Mydlo, 2001; Lee et al, 2007), where the tunica albuginea is the thinnest (Hsu et al, 1994).

Diagnosis and Imaging. The diagnosis of penile fracture is often straightforward and can be made reliably by history and physical examination. Patients usually describe a cracking or popping sound as the tunica tears, followed by pain, rapid detumescence, and discoloration and swelling of the penile shaft. If Buck fascia remains intact, the penile hematoma remains contained between the skin and tunica, resulting in a typical “eggplant deformity.” If Buck fascia is disrupted, hematoma can extend to the scrotum, perineum, and suprapubic regions (Fig. 101-1 on the Expert Consult website). The swollen, ecchymotic phallus often deviates to the side opposite the tunical tear because of hematoma and mass effect. The fracture line in the tunica albuginea may be palpable. Because fear and embarrassment are common, the patient’s presentation to the emergency department or clinic is sometimes significantly delayed.

The incidence of urethral injury is significantly higher in the United States and Europe (20%) than in Asia, the Middle East, and the Mediterranean region (3%), probably owing to the different etiology—intercourse trauma versus self-inflicted injury (Eke, 2002;

Figure 101-1. Eggplant deformity—the classic appearance of a penile fracture sustained during intercourse, with hematoma of the penile shaft and ecchymosis extending into the scrotum.

Figure 101-3. A, Ultrasound examination demonstrates ruptured tunica albuginea (arrow) in a patient with a suspected penile fracture. B, Hematoma adjacent to ruptured tunica.

Zargooshi, 2009; Jack et al, 2004; Derouiche et al, 2008). Most urethral injuries are associated with gross hematuria, blood at the meatus (Fig. 101-2 on the Expert Consult website), or inability to void, although the absence of these findings does not definitively rule out urethral injury (Tsang and Demby, 1992; Mydlo, 2001; Jack et al, 2004; Koifman et al, 2010). Given that urethral injury occurs frequently, preoperative urethrography should be considered when urethral injury is suspected. However, because urethrography can be time-consuming and inaccurate (Kamdar et al, 2008), intraoperative flexible cystoscopy is now often performed routinely just before catheter placement at the time of penile exploration when urethral injury is suspected.

The typical history and clinical presentation of penile fracture usually make adjunctive imaging studies unnecessary. However, when the history and physical examination are equivocal for penile fracture, ultrasonography can establish the diagnosis (Koifman et al, 2010). Ultrasonography (Fig. 101-3) has become the preferred imaging study to evaluate for penile fracture because it is rapid, readily available, noninvasive, inexpensive, and accurate. Penile ultrasound is most useful for ruling out fracture in patients with low clinical suspicion or to identify the location of the tear, potentially guiding the choice of incision (El-Assmy et al, 2011).

Magnetic resonance imaging (MRI) has been reported to be a noninvasive and accurate alternative means of demonstrating disruption of the tunica albuginea (Fedel et al, 1996; Uder et al, 2002). However, because of the expense, limited availability, and time requirements involved, MRI has not been employed widely for the evaluation of patients with symptoms and physical findings suggestive of penile fracture. Cavemosography is discouraged in the evaluation of a suspected penile fracture because it is time-consuming and unfamiliar to most urologists and radiologists (Beysel et al, 2002; Morey et al, 2004).

False fracture has been reported in patients who present with penile swelling and ecchymosis, and some even describe the classic "snap-pop" or rapid detumescence typically associated with fracture (Feki et al, 2007). Physical examination may be inadequate for definitive diagnosis of a corporeal tear in these circumstances (Shah et al, 2003). Surgical exploration (Fig. 101-4 on the Expert Consult website) or evaluation with MRI should be considered (El-Assmy et al, 2010). Another condition that may mimic penile fracture is rupture of the dorsal penile artery or vein during sexual intercourse (Armenakas et al, 2001; Bar-Yosef et al, 2007).

Management. Multiple contemporary publications recommend that suspected penile fractures be promptly explored and surgically repaired. Because most penile fractures occur ventrally or laterally, a ventral vertical penoscrotal incision is usually pre-

Figure 101-5. Surgical exploration through a ventral vertical incision showing excellent exposure of the site of the tunical tear and associated urethral injury.

ferred for direct exposure to the fracture (Fig. 101-5) (Mazaris et al, 2009). Alternatively, small lateral incisions may be used for localized hematomas or palpable tunical defects (El-Bahnasawy and Gomha, 2000; Nasser and Mostafa, 2008). The distal circumcising incision may be appropriate when the location of the fracture is uncertain because it provides exposure to all three penile compartments. Closure of the tunical defect with interrupted 2-0 or 3-0 absorbable sutures is recommended; deep corporeal vascular ligation and excessive debridement of the delicate underlying erectile tissue should be avoided.

Induction of an artificial erection with saline or colored dye may aid in locating the corporeal laceration (Shaer, 2006). Partial urethral injuries should be oversewn with fine absorbable suture over a urethral catheter. Complete urethral injuries should be debrided, mobilized, and repaired in a tension-free fashion over a catheter (Fig. 101-6). Therapy with broad-spectrum antibiotics and 1 month of sexual abstinence are recommended. In uncircumcised patients, the distal circumcising incision may place the distal prepuce at risk for ischemia. Although a ventral vertical incision is preferred, if a distal circumcising incision is required, performing limited circumcising at the conclusion of the repair should be strongly considered.

Outcome and Complications. Surgical reconstruction results in faster recovery, decreased morbidity, lower complication rates, and

Figure 101-2. A, Large arrow indicates pronounced ecchymosis and swelling in this patient with a penile fracture sustained during intercourse. Small arrow indicates blood at the urethral meatus. B, During surgical exploration and repair, urethral laceration with an exposed Foley catheter is noted (large arrow). Small arrow indicates laceration of corpus cavernosum.

Figure 101-6. A, Completely transected urethra secondary to penile fracture. Repair of bilateral tunical rupture was performed previously. B, Anastomotic repair of the urethra.

lower incidence of long-term penile curvature (Nicolaisen et al, 1983; Orvis and McAninch, 1989; Hinev, 2002; El-Taher et al, 2004; Muentener et al, 2004). Although repair results in penile curvature in less than 5% of patients (El Atat et al, 2008), conservative management of penile fracture has been associated with penile curvature in more than 10% of patients, abscess or debilitating plaques in 25% to 30%, and significantly longer hospitalization times and recovery (Meares, 1971; Nicolaisen et al, 1983; Kalash and Young, 1984; Orvis and McAninch, 1989). Zargooshi (2009) reported in a surgical series of 352 patients that surgical management of penile fractures resulted in erectile function in nearly all patients. Although surgery is better than conservative management, surgical delay of up to 7 days after the time of injury does not adversely affect the results of repair (El-Assmy et al, 2011; Kozacioglu et al, 2011).

Gunshot and Penetrating Injuries

Gunshot Wounds. Most penetrating wounds to the genitalia are due to gunshots (Mohr et al, 2003; Phonsombat et al, 2008; Bjurlin et al, 2013), and most require surgical exploration. Treatment principles include immediate exploration, copious irrigation, excision of foreign matter, antibiotic prophylaxis, and surgical closure. Gunshot injuries to the phallus are rarely isolated wounds—nearly all victims have significant associated injuries, including abdominal, pelvic, lower extremity, vascular, or additional genitourinary injuries (Bandi and Santucci, 2004; Kunkle et al, 2008; Najibi et al, 2010). Excellent cosmetic and functional outcomes can be expected with immediate reconstruction (Gomez et al, 1993; Cavalcanti et al, 2006). An artificial erection may be induced to ensure penile straightness, and plication techniques may be used to correct any curvature resulting from closure of a large corporeal injury (Kunkle et al, 2008).

Urethral injuries have been reported in 15% to 50% of penile gunshot wounds (Miles et al, 1990; Goldman et al, 1996; Mohr et al, 2003; Cinman et al, 2013). Retrograde urethrography should be strongly considered in any patient with penetrating injury to the penis, especially with high-velocity missile injuries, blood at the meatus, or difficulty voiding and when the trajectory of the bullet was near the urethra (Goldman et al, 1996; Mohr et al, 2003; Bandi and Santucci, 2004; Phonsombat et al, 2008; Cerwinka and Block, 2009). Alternatively, intraoperative retrograde urethral injection of methylene blue or indigo carmine may identify the site of injury and the adequacy of closure. If a catheter has already been placed, pericatheter injection may help to ascertain urethral integrity.

Urethral injuries resulting from penetrating trauma should be closed primarily by use of standard urethroplasty principles

whenever possible—excellent results have been reported (Miles et al, 1990; Bandi and Santucci, 2004). Patients with urethral injury and extensive tissue damage from high-velocity weapons or close-range shotgun blasts may require staged repair and suprapubic urinary diversion (Bandi and Santucci, 2004), especially injuries located in the penile urethra (Cavalcanti et al, 2006).

Animal and Human Bites. The morbidity of animal bites is directly related to the severity of the initial wound. Most victims are boys, and dog bites are the most common injury (Gomes et al, 2001; Van der Horst et al, 2004). Infectious complications are unusual because treatment is sought early. Initial management of dog bites includes copious irrigation, debridement, and immediate primary closure along with prophylactic use of broad-spectrum antibiotic (Wolf et al, 1993; Cummings and Boullier, 2000; Bertozzi et al, 2009). Tetanus and rabies immunizations should be used as appropriate. Because of the risk of polymicrobial infection and the antimicrobial susceptibilities of typical organisms, recommended empirical antimicrobial therapy choices include a β -lactam antibiotic with a β -lactamase inhibitor (i.e., amoxicillin-clavulanic acid), a second-generation cephalosporin with anaerobic efficacy (i.e., cefoxitin, cefotetan), or clindamycin with a fluoroquinolone (Talan et al, 1999).

Human bites produce contaminated wounds that often should not be closed primarily. Most individuals with human bite injuries seek medical attention after a substantial delay and are more likely to present with gross infection. Empirical antibiotic administration is warranted with amoxicillin/clavulanic acid or moxifloxacin (Talan et al, 2003).

Amputation

Traumatic amputation of the penis, although rare, is usually the result of genital self-mutilation. Psychosis is present in 65% to 87% of patients performing genital self-mutilation (Greilshheimer and Groves, 1979; Aboseif et al, 1993; Romilly and Isaac, 1996). Psychiatric consultation should be sought in all such cases.

Reconstruction of the urethra and reanastomosis of the corporeal bodies with microsurgical repair of dorsal penile vessels and nerves achieves remarkably good results. Patients should be transferred to a facility with microsurgical capabilities; however, if such a facility is unavailable, macroscopic anastomosis of the urethra and corporeal bodies can be performed with good erectile results, albeit with potential compromise of sensation and skin loss (Bhanganada et al, 1983; Razzaghi et al, 2009). Every attempt should be made to locate, clean, and preserve the severed portion in a “double bag” technique. The distal penis should be rinsed in saline solution, wrapped in saline-soaked gauze, and sealed in a

sterile plastic bag, and the bag should be placed into an outer bag with ice or slush (Jeziar et al, 2001). Hypothermic injury to the amputated segment can occur if it is in direct contact with ice for a prolonged period. Successful reimplantation is possible after 16 hours of cold ischemia time or 6 hours of warm ischemia (Lowe et al, 1991). If the severed part is unavailable, the penile stump should be formalized by closing the corpora and spatulating the urethral neomeatus, similar to a partial penectomy procedure for malignant disease.

Microvascular reconstruction of the dorsal arteries, vein, and nerves is the preferred method of repair for an amputated penis. Adequate erectile function is possible with microvascular reanastomosis and macroscopic replantation, with more than 50% of men able to achieve erection with either technique (Bhanganada et al, 1983; Lowe et al, 1991; Aboseif et al, 1993). However, complications such as urethral strictures, skin loss, and sensory abnormalities all are less common with microvascular repair (Jeziar et al, 2001).

Normal penile sensation returns in 0% to 10% of patients after macroscopic replantation (Bhanganada et al, 1983; Lowe et al, 1991), whereas sensation is present in more than 80% of patients with microscopic replantations (Jordan and Gilbert, 1989; Lowe et al, 1991; Jeziar et al, 2001). Penile skin necrosis, sometimes complete, is often a troublesome problem, although it is less common with microsurgical repair. This is because the blood supply of the skin is independent of the corporeal bodies and because without repair of the superficial vascular structures, the penile skin is essentially a free graft (Jeziar et al, 2001). Split-thickness skin grafts are applied when the native skin becomes necrotic (Ozturk et al, 2009). An alternative strategy is to denude the phallus of all skin and bury it in the scrotum, leaving the glans exposed, followed by separation of the structures after 2 months (Bhanganada et al, 1983; Jordan and Gilbert, 1989). Adjuvant techniques after penile replantation include the use of hyperbaric oxygen to promote healing (Landström et al, 2004; Zhong et al, 2007) or medical leeches on the penis after macroreplantation to augment venous outflow and decrease edema (Mineo et al, 2004).

KEY POINTS: STEP-BY-STEP APPROACH TO PENILE REATTACHMENT

- Suprapubic cystostomy
- Closure of the tunica albuginea with 3-0 absorbable suture
- Two-layer urethral closure over a catheter with fine absorbable suture
- Minimal dissection along the neurovascular bundle to identify severed vessels and nerves
- Microscopic anastomosis of the dorsal artery with 11-0 nylon
- Microscopic dorsal vein repair with 9-0 nylon
- Microscopic epineural repair of dorsal nerve with 10-0 nylon
- Skin coverage

Zipper Injuries

Zipper injuries to the penis more often happen to impatient boys or intoxicated men. Multiple maneuvers are available to free the entrapped skin and to remove the mechanism. After a penile block, the zipper slider and adjacent skin can be lubricated with mineral oil, followed by a single attempt to unzip and untangle the skin (Kanegaye and Schonfeld, 1993; Mydlo, 2000). The cloth material connected to the zipper can be incised with perpendicular cuts in between each zipper tooth to release the lateral support of the zipper, allowing the device to fall apart and release the trapped skin (Oosterlinck, 1981). A bone cutter or similar tool can be used to cut the median bar (diamond-shaped connection) of the slider. This maneuver allows separation of the upper and lower shields of the slider, and the entire zipper falls apart (Flowerdew et al, 1977; Saraf

and Rabinowitz, 1982). Also, a screwdriver may be placed between the upper and lower shields of the slider, and a twisting action separates the two shields from the median bar and unravels the zipper (Raveenthiran, 2007). Another technique involves cutting the anterior shield with a wire cutter (Maurice and Cherullo, 2013). Some children may require more than local anesthesia or sedation; circumcision or an elliptical skin excision can be performed in the operating room under anesthesia (Yip et al, 1989; Mydlo, 2000).

Strangulation Injuries

Accidental injuries with thread, hair, or rubber bands occur in children, but child abuse must be considered in such cases. Any child with unexplained penile swelling, erythema, or difficulty voiding should be examined closely for a hidden strangulating hair or string. Adults may place objects around the shaft as a means of sexual pleasure or to prolong an erection. The constricting device can reduce blood flow, cause edema, and induce ischemia; gangrene and urethral injury may develop in delayed presentations. Emergent treatment requires decompression of the constricted penis to allow blood flow and micturition. Depending on the constricting device, significant resourcefulness may be required of the physician.

String, hair, and rubber bands can be incised. Initial attempts to remove a solid constricting device causing penile strangulation involve lubrication of the shaft and foreign body and attempted direct removal. Edema distal to the strangulation often makes removal difficult. A string or latex tourniquet can be wrapped around the distal shaft to decrease swelling and to improve the odds of removing the device with lubrication. If the constricting object cannot be severed or removed, a string technique should be considered (Browning and Reed, 1969; Vahasarja et al, 1993; Noh et al, 2004). A thick silk suture or umbilical tape is passed proximally under the strangulation object and wound tightly around the penis distally toward the glans. The tag of suture or tape proximal to the ring is grasped; unwinding from the proximal end pushes the object distally. Glanular puncture with a needle or blade allows escape of dark trapped blood and improves the odds of removing the object with the string method (Browning and Reed, 1969; Noh et al, 2004).

Plastic constricting devices can be incised with a scalpel or an oscillating cast saw (Pannek and Martin, 2003), but metal objects present a more difficult challenge. Readily available hospital equipment (ring cutters, bolt cutters, dental drills, commercially available rotary tools, orthopedic and neurosurgical operative drills) may be inadequate to cut through heavy iron or steel items. The use of industrial drills, steel saws, hacksaws, saber saws, and high-speed electric drills has been reported (Perabo et al, 2002; Santucci et al, 2004). Occasionally, fire department and emergency medical services equipment may be required to cut through iron and steel rings. The phallus should be protected from thermal injury, sparks, and the cutting blade by use of tongue depressors, sponges, or malleable retractors; continuous saline irrigation may be used for cooling. Such elaborate undertakings are best accomplished in the operating room under anesthesia. If decompression is delayed and the patient is distended and unable to void, a suprapubic bladder catheter should be placed. Outcomes are generally good with device removal alone, although the surgeon should be prepared to consider reconstructive techniques such as skin grafting if the strangulation injury causes skin necrosis (Ivanovski et al, 2007).

Testis

Etiology. Although the testis is relatively protected by the mobility of the scrotum, reflexive cremasteric muscle contraction, and the tough fibrous tunica albuginea, blunt injury (usually the result of assault, sports-related events, and motor vehicle accidents) can result in rupture of the tunica albuginea, contusion, hematoma, dislocation, or torsion of the testis. Testicular injury results from blunt trauma in about 75% of cases (McAninch et al, 1984; Cass and Luxenberg, 1991), whereas penetrating injuries secondary to firearms, explosions, or impalement account for the remaining cases.

Although only 1.5% of blunt testis injury involves both gonads, about 30% of penetrating scrotal trauma results in bilateral injury (Cass and Luxenberg, 1988, 1991). Similar to penetrating urethral injuries, penetrating scrotal trauma (roughly 80%) usually involves neighboring structures, including the thigh, penis, perineum, bladder, urethra, or femoral vessels (Gomez et al, 1993; Cline et al, 1998; Simhan et al, 2012). In contemporary military conflicts, genital wounds account for a larger percentage of urologic injuries because of the powerful explosive weapons involved and absence of protective body armor over the genitalia (Thompson et al, 1998; Waxman et al, 2009). Blast injuries are typically associated with extensive scrotal skin loss, multiple projectile injuries of both testes, and concomitant extensive destruction of the lower extremities and abdomen.

Diagnosis. Rupture of the testis must be considered in all cases of blunt scrotal trauma. Most patients complain of exquisite scrotal pain and nausea. Swelling and ecchymosis are variable, and the degree of hematoma may not correlate with the severity of testicular injury; absence does not entirely rule out testicular rupture, and contusion without fracture can manifest as significant bleeding. Scrotal hemorrhage and hematocele along with tenderness to palpation often limit a complete physical examination. Concomitant urethral injury should be suspected and evaluated when examination reveals blood at the meatus or if the mechanism of injury or hematuria suggests this possibility. Penetrating injuries mandate careful examination of surrounding structures, especially the femoral vessels.

Ultrasonography can be helpful to assess the integrity and vascularity of the testis in equivocal cases. Ultrasonography is rapid, readily available, and noninvasive. Because it may be operator dependent, false-positive and false-negative studies range from 56% to 94% (Fournier et al, 1989; Corrales et al, 1993; Herbener, 1996; Dreitlein et al, 2001). Ultrasound findings suggestive of testicular fracture include a heterogeneous echo pattern of the testicular parenchyma and disruption of the tunica albuginea (Fig. 101-7) (Micallef et al, 2001; Buckley and McAninch, 2006). Although ultrasonography may assist in detection of testicular fracture or hematoma (Guichard et al, 2008), a normal or equivocal ultrasound study should not delay surgical exploration when physical examination findings suggest testicular damage; definitive diagnosis is often made in the operating room. Although MRI may effectively demonstrate testicular integrity, its widespread use is not the norm because of expense, limited availability, and potential delay in definitive surgical care of the patient (Serra et al, 1998; Muglia et al, 2002; Kim et al, 2009).

Differential diagnosis of testicular fracture includes hematocele without rupture, torsion of the testis or an appendage, reactive

hydrocele, hematoma of the epididymis or spermatic cord, and intratesticular hematoma. A nonpalpable testis in a trauma patient should raise the possibility of dislocation outside the scrotum. This entity usually occurs after motorcycle crashes when extreme forces on the scrotum expel the testis into surrounding tissues such as the superficial inguinal pouch (50%) or to a pubic, penile, pelvic, abdominal, or perineal location (Schwartz and Faerber, 1994; Bromberg et al, 2003). Bilateral dislocation after trauma has been reported (Bromberg et al, 2003; O'Brien et al, 2004). Manual or surgical reduction of the displaced testis is indicated. Finally, approximately 5% of spermatic cord torsions are believed to be precipitated by trauma; torsion should be considered in all cases of significant scrotal pain without signs or symptoms of major scrotal trauma (Elsaharty et al, 1984; Manson, 1989; Lrhorfi et al, 2002).

Management. Early exploration and repair of testicular injury is associated with increased testicular salvage, reduced convalescence and disability, faster return to normal activities, and preservation of fertility and hormonal function (Kukadia et al, 1996). Minor scrotal injuries without testicular damage can be managed with ice, elevation, analgesics, and irrigation and closure in some circumstances.

The objectives of surgical exploration and repair are testicular salvage, prevention of infection, control of bleeding, and reduced convalescence. Transverse scrotal incision is preferable in most cases. The tunica albuginea should be closed with small absorbable sutures after removal of necrotic and extruded seminiferous tubules. Even small defects in the tunica albuginea should be closed because progressive swelling and intratesticular pressure can continue to extrude seminiferous tubules. Every attempt to salvage the testis should be performed; loss of capsule tissue may require removal of additional parenchyma to allow closure of the remaining tunica albuginea. A flap or graft of tunica vaginalis may be used to cover a large defect in the tunica albuginea in an otherwise salvageable testis (Fig. 101-8); synthetic grafts are not recommended for this purpose (Ferguson and Brandes, 2007). Significant intratesticular hematomas should be explored and drained even in the absence of testicular rupture to prevent progressive pressure necrosis and atrophy, delayed exploration (40%), and orchiectomy (15%) (Cass and Luxenberg, 1988). Significant hematoceles should also be explored, regardless of imaging studies, because up to 80% are caused by testicular rupture (Vaccaro et al, 1986; Buckley and McAninch, 2006).

Penetrating scrotal injuries should be surgically explored to inspect for vascular and vasal injury; the same principles of salvage, hemostasis, and reconstruction apply as in blunt trauma. The vas deferens is injured in 7% to 9% of scrotal gunshot wounds (Gomez et al, 1993; Brandes et al, 1995). The injured vas should be ligated with nonabsorbable suture, and delayed reconstruction should be performed if necessary. Approximately 30% of gunshot wounds injure both testes, and exploration of the contralateral testis should be considered, depending on the findings of physical examination and the path of the projectile.

Outcome and Complications. Nonoperative management of testicular rupture is frequently complicated by infection, atrophy, necrosis, chronic unrelenting pain, and delayed orchiectomy. Testicular salvage rates exceed 90% with exploration and repair within 3 days of injury (Del Villar et al, 1973; Schuster, 1982; Fournier et al, 1989; Cass and Luxenberg, 1991) versus orchiectomy rates threefold to eightfold higher with conservative management and delayed surgery (Cass and Luxenberg, 1991). Testicular salvage rates with conservative management are 33%, with delayed orchiectomy rates between 21% and 55% (Schuster, 1982; Cass and Luxenberg, 1991; McAleer and Kaplan, 1995). Approximately 45% of patients initially managed conservatively ultimately undergo surgical exploration for pain, infection, and persistent hematoma (Del Villar et al, 1973; Cass and Luxenberg, 1991). Convalescence and time of return to normal activities are significantly reduced after early surgical repair.

In contrast to blunt testis rupture, for which salvage rates are very high, penetrating testicular trauma has historically been associated with gonad salvage in only 32% to 65% of cases (Bickel et al, 1990;

Figure 101-7. Ultrasound examination demonstrates hypoechoic intratesticular areas (arrow) consistent with testicular rupture sustained by blunt trauma. Scrotal exploration revealed large hematocele and exposed seminiferous tubules.

Figure 101-8. A, Testicular rupture after blunt trauma. B, Reconstructed testis after debridement and closure. Arrow indicates placement of a tunica vaginalis graft.

Gomez et al, 1993; Brandes et al, 1995; Cline et al, 1998). Improved salvage rates of 75% have been reported in more recent civilian (Phonsombat et al, 2008; Simhan et al, 2012; Bjurlin, 2013) and combat series (Waxman et al, 2009). Most surgical patients have adequate preservation of hormonal and fertility function (Kukadia et al, 1996). Sperm production has been documented in men with appropriately repaired bilateral testis rupture and bilateral penetrating injuries (Pohl et al, 1968; Brandes et al, 1995).

Urologists may be consulted for opinion and guidance with regard to boys with a solitary testis who play a contact sport. Testicular injuries are exceedingly rare in boys involved in individual or team contact sports and recreational activities (McAleer et al, 2002; Wan et al, 2003a, 2003b). Parents should be appropriately counseled, and a protective cup device should be recommended. The American Academy of Pediatrics Committee on Sports Medicine and Fitness recommended that many factors be considered regarding whether to allow a child with a solitary testis to play sports; their recommendation was an unqualified yes in this circumstance (Committee on Sports Medicine and Fitness, 2001).

Genital Skin Loss

Etiology. Necrotizing gangrene secondary to polymicrobial infection in the genital area, or Fournier gangrene, is the most common cause of extensive genital skin loss (McAninch et al, 1984). Skin loss is iatrogenic, caused by the necessity for acute debridement of necrotic genital skin when the patient is seen initially.

Penile skin loss can result from traction by mechanical devices, such as farm or industrial machinery, or by suction devices, such as vacuum cleaners. Because the superficial penile tissue is loose areolar tissue, it is often torn free without damage to the underlying structures. Significant scrotal skin loss resulting from penetrating trauma is uncommon, but it has been seen more recently in battlefield explosive injuries (Fig. 101-9).

Penile burns, although rare, are often full-thickness burns because the penile skin is so thin (Horton and Dean, 1990). Constricting bands placed on the penis can result in significant skin loss, although a more common injury involves direct pressure necrosis under the band, which usually heals well with device removal alone.

Diagnosis and Initial Management. Although both cellulitis and Fournier gangrene are commonly associated with significant genital edema and erythema, skin ischemia is the hallmark of Fournier gangrene. The finding of loss of scrotal rugae is highly

Figure 101-9. Extensive loss of scrotal skin from explosive blast injury. Note numerous concomitant shrapnel injuries to the thigh.

suggestive of tissue necrosis. Scrotal ultrasonography (Kane et al, 1996; Morrison et al, 2005) and CT may reveal subcutaneous air, a helpful indicator of necrotizing infection (Fig. 101-10).

In most cases of Fournier gangrene, multiple debridements of ischemic or frankly necrotic skin are required over a period of several days until active infection is controlled. Wounds are treated with frequent wet-to-dry dressing changes or with vacuum-assisted closure therapy (Czymek et al, 2009) until primary coverage is planned. Inspection at least daily by the surgical team is mandatory. Suprapubic urinary diversion should be strongly considered for extensive injuries to simplify wound care and to prevent urethral

Figure 101-10. A, Large erythematous scrotum with central necrosis suggestive of necrotizing infection. B, Computed tomography scan reveals subcutaneous air in the scrotum (arrow) secondary to Fournier gangrene.

complications related to prolonged catheterization. Hyperbaric oxygen treatment has been advocated as an adjunctive measure to promote wound healing, although we do not recommend this owing to the considerable increased expense and logistical complexity in the absence of proven benefit (Mindrup et al, 2005).

Genital burns are largely treated similar to other burns, with early resection of burn eschar and coverage with split-thickness skin grafts when possible. Partial-thickness skin loss or genital burns may be treated with silver sulfadiazine cream. For deep penile electrical burns, a conservative approach is warranted because the ultimate outcome usually is autopenectomy and/or death as a result of extensive concurrent injuries (Medendorp et al, 2007).

Penile Reconstruction

In selected uncircumcised patients, mobilization of redundant foreskin may allow primary closure of middle to distal penile skin loss (Horton and Dean, 1990). Scrotal rotation flaps can be used for more proximal defects if skin loss is limited, but the hair-bearing nature of scrotal skin risks an unacceptable cosmetic result (Zhao et al, 2009). Local flaps, such as from the abdomen and thigh, also can be used but are cosmetically inferior to split-thickness skin grafts. Skin coverage with avulsed skin should be avoided because it often becomes necrotic.

Thick (0.012- to 0.015-inch), nonmeshed, split-thickness skin grafts (McAninch et al, 1984) are preferred for penile reconstruction. Meshed grafts can be used but have a tendency to contract and are cosmetically inferior to unmeshed grafts. Grafts are usually harvested from the anterior thigh with a pneumatic dermatome. If grafts are to be used, care must be taken to remove any subcoronal skin remaining after debridement. Lymphatic obstruction of this distal foreskin, if it is not excised, results in circumferential lymphedema (McDougal, 2003). Graft stabilization in the immediate postoperative period may be achieved with either a tie-over-bolster technique or with a circumferential vacuum dressing (Weinfeld et al, 2005; Senchenkov et al, 2006). Skin grafts placed on the penile shaft never regain normal sensation (Horton and Dean, 1990), although sexual function is often preserved because of intact sensation in the glans.

Scrotal Reconstruction

Scrotal skin loss defects of up to 50% can often be closed directly. For extensive injuries, the testes may be placed in thigh pouches,

treated with wet dressings, or placed under vacuum pressure dressings until reconstruction (Cummings and Boullier, 2000; Gomes et al, 2001; Cuccia et al, 2009). Thigh pouches are not recommended initially, until the infection is stabilized, because transmission of the infectious process into uninvolved tissues may occur. During scrotal reconstruction, local skin flaps should be mobilized initially to cover as much of the tissue defect as possible (Fig. 101-11 on the Expert Consult website). Meshed split-thickness skin grafts can be employed for remaining reconstruction. In addition to providing an excellent cosmetic result, meshing allows exudate to escape from the interstices, improving graft take. The spermatic cords and testes are sewn together in multiple areas before grafting to prevent a bifid neoscrotum (Tan et al, 2011). The neoscrotum may appear unnaturally tight initially, but after 6 to 12 months the testes eventually occupy a more natural dependent position. Thigh flaps can be used to reconstruct the scrotum when the testes have been buried in the thighs after traumatic or surgical scrotal removal (Morey and McAninch, 1999). Fibrin sealant has proved useful as a tissue glue to promote healing and to reduce drainage during complex genital reconstruction cases (Morris et al, 2006).

KEY POINTS: GENITAL TRAUMA

- Although penile fracture usually can be diagnosed based on history and physical examination, penile ultrasonography is a readily available, inexpensive, rapid, and accurate imaging modality that may be useful to guide clinical management.
- Gunshot wounds to the penis should be repaired primarily to prevent deformity and erectile dysfunction.
- Animal bites should be irrigated, debrided, and closed primarily, whereas most human bites should be left open.
- Blunt scrotal injury can be evaluated by ultrasonography for testicular rupture. Penetrating scrotal injuries should undergo surgical exploration to assess and repair deep tissues and remove contamination.

BLADDER INJURIES

Etiology. The urinary bladder is generally protected from external trauma because of its deep location in the bony pelvis. Most blunt

Figure 101-11. A, Scrotal defect before final debridement and closure of left hemiscrotum for Fournier gangrene. Arrow indicates an inguinal counterincision made owing to extension of infection to the inguinal canal. B, Delayed primary closure. The right testis and tunica vaginalis were mobilized off the overlying scrotal tissue, which was then used to close the scrotal defect.

bladder injuries are the result of rapid-deceleration motor vehicle collisions, but many also occur with falls, crush injuries, assault, and blows to the lower abdomen. Disruption of the bony pelvis tends to tear the bladder at its fascial attachments, but bone fragments also can directly lacerate the organ. Other important causes of bladder rupture include penetrating trauma, iatrogenic surgical complications, and spontaneous rupture in patients with a history of neuropathic disease, preexisting bladder disease, or prior urologic surgery.

Bladder injuries that occur with blunt external trauma are rarely isolated injuries—80% to 94% of patients have significant associated nonurologic injuries (Cass, 1984; Volpe et al, 1999; Hsieh et al, 2002; Parry et al, 2003; Bjurlin et al, 2009). Mortality in these patients with multiple injuries is usually related to nonurologic injuries and ranges from 8% to 44% (Carroll and McAninch, 1984; Cass and Luxenberg, 1987; Corriere and Sandler, 1989; Volpe et al, 1999; Alli et al, 2003; Parry et al, 2003). **The most common associated injury is pelvic fracture, which is associated with 83% to 95% of bladder injuries** (Cass, 1989; Corriere and Sandler, 1989; Morey et al, 2001; Parry et al, 2003). Conversely, bladder injury has been reported to occur in only 5% to 10% of pelvic fractures (Cass, 1989; Peters, 1989; Aihara et al, 2002). Sudden force applied to a full bladder may result in a rapid increase in intravesical pressures and lead to rupture without pelvic fracture.

Penetrating bladder trauma also is associated with significant nonurologic injuries and mortality rate. Nearly half of all bladder injuries are iatrogenic (Dobrowolski et al, 2002); **obstetric and gynecologic complications are the most common causes of bladder injuries during open surgery** (Dobrowolski et al, 2002; Gomez et al, 2004).

Diagnosis. Extraperitoneal bladder injury is usually associated with pelvic fracture. Intraperitoneal injuries can be associated with pelvic fracture but are more commonly due to penetrating injuries or burst injuries at the dome by direct blow to a full bladder. Appropriate diagnostic imaging is important because of the marked influence on management.

Clinical Signs and Symptoms. Bladder rupture does not occur as an isolated, asymptomatic event in normal individuals. Conscious patients present with pronounced nonspecific symptoms such as suprapubic pain combined with inability to void. Physical signs include suprapubic tenderness, lower abdominal bruising, muscle guarding and rigidity, and diminished bowel sounds. Associated abdominal and pelvic injuries may mask bladder symptoms. Higher suspicion for bladder injury is similarly warranted in patients who are unresponsive because of intoxication or altered sensorium.

Immediate catheterization should be performed when blunt bladder rupture is suspected because **the most reliable indicator is gross hematuria, which is present in nearly all cases** (Iverson and Morey, 2001; Hsieh et al, 2002; Parry et al, 2003; Gomez et al, 2004). If blood is noted at the meatus or the catheter does not pass easily, retrograde urethrography should be performed first because urethral injuries occur concomitantly in 10% to 29% of patients with bladder rupture (Cass, 1989; Dobrowolski et al, 2002).

Radiographic Imaging. Imaging of the bladder is performed on the basis of clinical suspicion. After blunt external trauma, the absolute indication for immediate cystography is gross hematuria associated with pelvic fracture—approximately 29% of patients presenting with this combination of findings have bladder rupture (Morey et al, 2001). Relative indications for cystography after blunt trauma include gross hematuria without pelvic fracture and microhematuria with pelvic fracture. **The diagnosis of bladder rupture is extremely low in these atypical groups (e.g., 0.6% in patients with pelvic fracture and microhematuria), but the index of suspicion should be raised by associated clinical indicators of bladder injury.** Conversely, penetrating injuries of the buttock, pelvis, or lower abdomen with any degree of hematuria warrant cystography.

Retrograde or stress cystography is nearly 100% accurate for bladder injury if performed appropriately. The bladder should be filled in cooperative and conscious patients to a sense of discomfort

KEY POINTS: CLINICAL INDICATORS OF BLADDER INJURY

- Suprapubic pain or tenderness
- Free intraperitoneal fluid on CT or ultrasound examination
- Inability to void or low urine output
- Clots in urine or clots noted in bladder on CT
- Enlarged scrotum with ecchymosis
- Abdominal distention or ileus

and otherwise to 350 mL. For a plain film technique, three images are obtained: one before administration of a contrast agent, one full-bladder anteroposterior film, and one drainage film. Posterior extravasation of the contrast medium can be missed without a drainage film. Significant bladder distention is required to visualize small tears. False-negative studies have been reported with retrograde instillation of only 250 mL (Peters, 1989; Morey and Carroll, 1997). Although hematuria and mechanism of injury mandate consideration of upper tract imaging studies, upper and lower urinary tract injuries are almost never coincident (0.4%) (Cass and Luxenberg, 1990).

A dense, flame-shaped collection of contrast material in the pelvis is characteristic of extraperitoneal extravasation (Fig. 101-12). Depending on fascial integrity, contrast material may extend beyond the confines of the pelvis and be visualized in the retroperitoneum, scrotum, phallus, thigh, or abdominal wall. The amount of extravasation is not always proportional to the extent of bladder injury. Intraperitoneal extravasation is identified when contrast material outlines loops of bowel and/or the lower lateral portion of the peritoneal cavity.

Because CT is now routinely used to assess trauma patients, concomitant CT cystography is frequently selected as a more efficient means to assess the bladder. CT cystography is as accurate and reliable as plain film cystography in evaluation of suspected bladder injury (Fig. 101-13), as long as the bladder is filled in retrograde fashion with contrast material diluted to 2% to 4% (6:1 with saline) to a volume of 350 mL (Peng et al, 1999; Hsieh et al, 2002). Drainage films are not required after CT cystography because the

Figure 101-12. Plain film cystogram reveals extraperitoneal bladder rupture with extravasation into the scrotum. Surgical exploration revealed anterior bladder neck and prostatic urethral laceration.

retrovesical space can be well visualized with axial images (Morey and Carroll, 1997). Dilution of the contrast material is mandatory because undiluted contrast material is so dense that the CT quality is compromised by scatter artifact. **Clamping the urethral catheter in an attempt to allow antegrade distention of the bladder by intravenous contrast medium is inadequate for diagnosis of bladder rupture—retrograde filling is required.** Conventional abdominal CT of a trauma patient may show findings suggestive of bladder injury, but it is not considered to be adequate for bladder evaluation without retrograde contrast distention (Mee et al, 1987; Udekwe et al, 1996; Hsieh et al, 2002).

Management. The usual treatment of uncomplicated extraperitoneal bladder ruptures, when conditions are ideal, is conservative management with urethral catheter drainage alone (Fig. 101-14). A large-bore (22-Fr) Foley catheter should be used to promote adequate drainage; if output is poor, fluoroscopic cystography should be considered to ensure proper catheter placement. Cystography is necessary to verify complete healing before catheter removal 14 days after injury; occasionally, extravasation may persist

for several additional weeks, but it resolves with continuation of urethral catheter drainage, after which radiographic confirmation of healing is essential. Bone spicules within the bladder wall (Fig. 101-15 on the Expert Consult website) may compromise healing. Antimicrobial agents are instituted on the day of injury and continued for at least 1 week to prevent infection of the pelvic hematoma.

Several authors (Cass, 1989; Kotkin and Koch, 1995) have reported fewer complications, such as fistula, failure to heal, clot retention, and sepsis, with open repair (5% overall) versus conservative management (12% overall). For this reason, blunt extraperitoneal injuries warrant immediate open repair to prevent complications such as fistula, abscess, and prolonged leak in the presence of any complicating features. If a patient whose condition is stable is undergoing exploratory laparotomy for other associated injuries or internal fixation of pelvic fracture, it is prudent to perform surgical repair of the extraperitoneal rupture at the same setting. The anterior bladder wall is entered, and the tear is closed intravesically with absorbable suture. The perivesical pelvic hematoma should not be disturbed. When internal fixation of pelvic fractures is performed, concomitant bladder repair is recommended because urine leakage from the injured bladder onto the orthopedic fixative hardware is prevented, reducing the risk of hardware infection. Drainage of the repaired bladder can be safely accomplished with a large-bore Foley catheter alone, and cystography performed 1 week after repair should verify bladder healing.

Figure 101-13. Computed tomography cystogram demonstrates contrast material surrounding loops of bowel consistent with intraperitoneal bladder rupture.

KEY POINTS: INDICATIONS FOR IMMEDIATE REPAIR OF BLADDER INJURY

- Intraperitoneal injury from external trauma
- Penetrating or iatrogenic nonurologic injury
- Inadequate bladder drainage or clots in urine
- Bladder neck injury
- Rectal or vaginal injury
- Open pelvic fracture
- Pelvic fracture requiring open reduction and internal fixation
- Selected stable patients undergoing laparotomy for other reasons
- Bone fragments projecting into bladder

Figure 101-14. A, Dense flame-shaped pattern of contrast extravasation in the pelvis secondary to extraperitoneal bladder rupture. B, Repeat cystogram in the same patient after 2 weeks of catheter drainage shows a completely healed bladder.

Figure 101-15. Computed tomography cystogram of a patient with extraperitoneal bladder rupture after a motor vehicle/pedestrian collision and extensive pelvic fracture. *Arrow* indicates a fragment of bone in the bladder, removed at the time of laparotomy and repair of the bladder.

Figure 101-16. A, Intraoperative image of laparoscopic bladder repair, with a flexible cystoscope inside the bladder. B, Appearance of bladder after two-layer closure.

All penetrating or intraperitoneal injuries resulting from external trauma should be managed by immediate operative repair. In a national study of patients with bladder trauma, operative repair was associated with a 59% reduction in mortality (Deibert and Spencer, 2011). These injuries are often larger than suggested on cystography and are unlikely to heal spontaneously, and continued leak of urine causes a chemical peritonitis. Although most injuries are repaired with open surgery, select patients may undergo laparoscopic repair (Fig. 101-16) (Kim et al, 2008). When bladder injuries are explored after penetrating trauma without preliminary imaging, the ureteral orifices should be inspected for clear efflux; ureteral integrity also may be ensured by intravenous administration of indigo carmine or methylene blue or retrograde passage of a ureteral catheter. Any penetrating injury involving the ureteral orifice or intramural ureter warrants primary closure with stented reimplantation of the ureter. A perivesical drain should be employed. In patients with intraperitoneal rupture, antimicrobial agents are administered for 3 days in the perioperative period only. If the bladder has been repaired, a cystogram is obtained 7 to 10 days after surgery (Corriere and Sandler, 1989). Several more recent studies have shown that suprapubic tube drainage provides no benefit over urethral catheter drainage alone (Volpe et al, 1999; Alli et al, 2003; Parry et al, 2003), although maximal urinary drainage using both is recommended when complex injuries are encountered. When concurrent rectal or vaginal injuries exist, the organ walls should be separated, overlapping suture lines should be avoided, and every attempt should be made to interpose viable tissue in between the repaired structures. Fibrin sealant injected over the bladder wall closure may help reduce complications when intervening tissue is unavailable (Evans et al, 2003).

Outcomes and Complications. Prompt diagnosis and appropriate management of bladder injuries promote excellent results and minimal morbidity. Serious complications are usually associated with delayed diagnosis or treatment because of misdiagnosis, delayed presentation, or complex injuries resulting from devastating pelvic trauma. Unrecognized bladder injuries may manifest as acidosis, azotemia, fever and sepsis, low urine output, peritonitis, ileus, urinary ascites, or respiratory difficulties. Unrecognized bladder neck, vaginal, and rectal injury associated with the bladder rupture can result in incontinence, fistula, stricture, and difficult delayed major reconstruction. Severe pelvic fractures may cause a transient or permanent neurologic injury and result in voiding difficulties despite an adequate bladder repair.

URETHRAL INJURIES

Posterior Urethral Injuries

Etiology. Urethral disruption injuries typically occur in conjunction with multisystem trauma from vehicular accidents, falls, or industrial accidents. Fracture of the anterior pelvic ring or pubic diastasis are almost always present when urethral disruption is encountered, and a greater degree of displacement has been correlated to a higher risk of urethral injury (Basta et al, 2007). “Straddle fractures” (Fig. 101-17 on the Expert Consult website) involving all four pubic rami and fractures resulting in vertical and rotational pelvic instability are associated with the highest risk of urologic injury (Mundy, 1996; Koraitim, 1999; Brandes and Borelli, 2001). Urethral injury has been reported to occur in approximately 10% of male patients and up to 6% of female patients with pelvic fractures (Koraitim, 1999; Black et al, 2006). Girls younger than age 17 years have a higher risk of urethral injury compared with women, perhaps owing to greater compressibility of the pelvic bones (Hemal et al, 1999).

Because the posterior urethra is densely adherent to the pubis via the urogenital diaphragm and the puboprostatic ligaments, the bulbomembranous junction is more vulnerable to injury during pelvic fracture than the prostatomembranous junction (Colapinto and McCallum, 1977; Brandes and Borelli, 2001). Endoscopic and urodynamic evaluation has confirmed that the membranous urethral sphincter complex tends to remain functionally intact while being avulsed vertically, posteriorly, or laterally from the underlying bulb (Mundy, 1997; Andrich and Mundy, 2001). In children, injuries are less common (Tarman et al, 2002) but are more likely to extend proximally to the bladder neck because of the rudimentary nature of the prostate (Devine et al, 1989; Al-Rifaei et al, 1991; Boone et al, 1992).

Diagnosis

Examination. Urethral disruption is heralded by the triad of blood at the meatus, inability to urinate, and palpably full bladder. Because these and other classic findings, such as a “high-riding” prostate or a “butterfly” perineal hematoma, may frequently be absent (Sandler and Corriere, 1989; Esposito et al, 2005), urethral disruption is often first detected when a urethral catheter cannot be placed by the emergency department trauma team or when it is misplaced into a pelvic hematoma. Pelvic hematoma often obscures the prostatic contour, resulting in a misdiagnosis of

Figure 101-17. Anteroposterior film of the pubis shows a straddle fracture involving all four pubic rami (*arrows*) in a patient with a posterior urethral disruption in whom initial perineal posterior urethroplasty failed because of severe bone distortion. Reconstruction was successfully performed by an abdominoperineal technique.

Figure 101-18. Pelvic fracture urethral disruption injury and marked vulvar edema and ecchymosis in a female patient.

Figure 101-19. Retrograde urethrogram in a patient with a pelvic fracture shows complete disruption of the posterior urethra.

impalpable prostate (Koraitim et al, 1996). Although much more rarely than male patients, female patients also may develop proximal urethral avulsion injuries. They present with vulvar edema (Fig. 101-18) and blood at the vaginal introitus, indicating the need for careful vaginal examination in all female patients with pelvic fracture (Perry and Husmann, 1992).

Urethrography. When blood at the urethral meatus is discovered, an immediate retrograde urethrogram should be performed to rule out urethral injury (Fig. 101-19). A small-bore (16-Fr) urethral catheter is placed unlubricated 1 cm into the fossa navicularis, and the balloon is filled with 1 cm of water to achieve a snug fit (Sandler and Corriere, 1989). Alternatively, a Brodney clamp or rolled gauze bandage can be used to provide penile traction. Patients should be placed in an oblique or lateral decubitus position, and it is preferable to perform the study under fluorography when it is available; 25 mL of contrast medium is injected gently by a 60-mL catheter-tip syringe, and the film is taken during injection. Direct inspection by urethroscopy is suggested in lieu of urethrography in female patients with suspected urethral injury (Perry and Husmann, 1992; Koraitim, 1999).

Initial Management

Immediate Open Reconstruction. Immediate anastomotic reconstruction of posterior urethral disruption injuries in men has been

Figure 101-20. Initial management of urethral disruption injury in a female patient with suprapubic catheter drainage alone leads to complete urethral obliteration. This injury was successfully reconstructed via delayed retropubic approach.

abandoned because of its association with unsatisfactory outcomes, such as impotence and incontinence, stricture formation, and operative blood loss (Webster et al, 1983; Koraitim et al, 1996). In cases of female urethral disruption related to pelvic fracture, most authorities suggest immediate primary repair, or at least urethral realignment over a catheter, to avoid subsequent urethrovaginal fistulae or urethral obliteration (Fig. 101-20) (Koraitim et al, 1996; Dorairajan et al, 2004; Black et al, 2006). Concomitant vaginal lacerations also must be closed acutely to prevent vaginal stenosis. Delayed reconstruction is problematic because the female urethra is too short (about 4 cm) to be amenable for mobilization during an anastomotic repair when it becomes embedded in scar (Podesta and Jordan, 2001); however, we have found that a suprapubic approach with partial pubectomy provides excellent exposure enabling female bladder neck reconstruction.

Suprapubic Cystostomy. Immediate suprapubic tube placement remains the standard of care in men with posterior urethral injuries. Placement may be accomplished through a small infraumbilical incision, which allows inspection and repair of the bladder and proper placement of a large-bore catheter at the bladder dome. Trocar suprapubic tube placement is safe and expedient when the bladder is obviously distended and no other indications for surgery exist; however, over the long term, smaller “punch” suprapubic tubes are less robust, tending to fracture or become obstructed with debris and often requiring urgent replacement.

Increasingly, patients with pelvic ring fracture undergo early surgical fixation by orthopedists to decrease bleeding, improve healing, and speed ambulation (Connor et al, 2003). Although orthopedists frequently suggest that a suprapubic tube not be placed if anterior pubic hardware is used in pelvic fracture repair because of concern that the suprapubic tube will lead to hardware infection (Patterson, 1995), we and others (Borrelli and Brandes, 2004; Bepple et al, 2007) have repeatedly found that suprapubic cystostomy can be used safely without complications throughout the course of care (Fig. 101-21 on the Expert Consult website). We use a large-bore (24-Fr) Foley catheter placed high in the bladder and tunneled through the skin as high as possible on the lower abdominal midline to keep the tube away from the plated symphysis.

Figure 101-21. A, Defect in the urethra (*arrow*) seen on an antegrade urethrogram in a patient after pelvic fracture urethral disruption and internal fixation of anterior pelvic fracture. B, Postoperative voiding urethrogram demonstrates normal-caliber urethra after perineal urethroplasty.

Primary Realignment. An attempt at primary realignment of the distraction with a urethral catheter is reasonable in patients whose condition is stable (Elliott and Barrett, 1997) and can be done either acutely or within several days of injury. We prefer a simple technique consisting of passing a coude catheter antegrade from an anterior cystostomy to the urethral meatus, then tying it to another catheter that is drawn back into the bladder. Various more elaborate approaches have been described, frequently with retrograde and antegrade flexible cystoscopes (Follis et al, 1992; Routt et al, 1996; Elliott and Barrett, 1997; Porter et al, 1997; Asci et al, 1999; Mouraviev et al, 2005; Hadjizacharia et al, 2008), although we have observed that prolonged endoscopic realignment attempts risk infection of the pelvic hematoma (Morey et al, 1999) and cannot be recommended.

When the urethral catheter is removed after 4 to 6 weeks, it is imperative to retain a suprapubic catheter because many patients, despite realignment, will develop posterior urethral stenosis. If the patient voids satisfactorily through the urethra, the suprapubic catheter can be removed 7 to 14 days later. Primary realignment sometimes may allow healing without stricture (Elliott and Barrett, 1997; Leddy et al, 2012), but mild stenosis 1 to 2 cm in length develops in many patients (Kotkin and Koch, 1996; Routt et al, 1996; Asci et al, 1999). Patients managed with suprapubic tubes alone virtually always develop complete stenosis requiring posterior urethroplasty (Kotkin and Koch, 1996; Mouraviev et al, 2005). Although realignment may not always prevent symptomatic stenosis, it may allow resultant strictures to be managed endoscopically or ease the difficulty of open posterior urethroplasty by bringing the prostate and urethra into alignment and shortening the length of the stricture (Mouraviev et al, 2005; Hadjizacharia et al, 2008; Koraitim, 2012).

Incomplete urethral tears are best treated by stenting with a urethral catheter. We and others (Al-Ali and Husain, 1983; Mundy, 1991; Kotkin and Koch, 1996) have not seen any evidence that a gentle attempt to place a urethral catheter can convert an incomplete into a complete transection. Caution is warranted because misplacement outside the bladder is possible; radiographic confirmation of adequate positioning is imperative. In no case is traction used after urethral catheter placement; it is unnecessary and may cause incontinence (Asci et al, 1999).

Complex Injuries

Some authors advocate open exploration with realignment in cases of high-riding or "pie-in-the-sky" bladder or associated bladder neck tear in male patients (Webster et al, 1983). Associated rectal

injuries require open exploration, repair, irrigation, and placement of drains.

Delayed Reconstruction

In posterior urethral disruption, the rupture defect between the two severed ends fills with scar tissue, resulting in a complete lack of urethral continuity. This separation is not a stricture; it is a true urethral rupture defect filled with fibrosis. At 3 months, scar tissue at the urethral disruption site is stable enough to allow posterior urethroplasty to be undertaken safely, provided that associated injuries are stabilized and the patient is ambulatory. Suprapubic cystostomy drainage should be maintained until the associated injuries have healed and the patient can be appropriately positioned for the reconstructive procedure.

Preoperative Evaluation. Before the reconstructive procedure is planned, imaging studies are necessary to delineate the characteristics of the urethral rupture defect. A cystogram and retrograde urethrogram should be obtained simultaneously ("up-and-down-ogram," Fig. 101-22). The patient is asked to attempt to void with the bladder filled. Ideally, the prostatic urethra should be visualized as the bladder neck opens, enabling measurement of the distance between the severed urethral ends. If the bladder neck does not open, flexible endoscopy should be used to supplement radiographic imaging (Mundy, 1997). It is uncertain whether the appearance of the bladder neck on preoperative imaging correlates with bladder neck behavior postoperatively (Mundy, 1997; Koraitim, 2010), making it difficult to predict bladder neck incompetence or obstruction. MRI has been used successfully to define the length of the defect and to determine the extent and direction of urethral dislocation (Dixon et al, 1992) and the extent of prostatic displacement, and it may help in planning the surgical approach (Koraitim and Reda, 2007).

Endoscopic Treatments. Endoscopic treatments such as direct-vision internal urethrotomy are best reserved for selected short urethral stenoses, such as partial distraction injuries for which early catheterization achieved urethral continuity. In most cases, when preoperative evaluation indicates defects 1 cm or longer, endoscopic procedures such as cutting through the pelvic scar to provide a channel between the two ends of the avulsed urethra ("cut-to-the-light" procedure) are ineffective and have no advantage other than reduced operative time (Levine and Wessels, 2001); aggressive endoscopic treatments have been associated with complications such as coring of a false passage that inadvertently bypasses the bladder neck (Turner-Warwick, 1989). Cut-to-the-light or similar core-through procedures typically require multiple

Figure 101-22. A, Combined cystogram and urethrogram 4 months after pelvic fracture shows complete posterior urethral disruption injury. B, Postoperative appearance reveals normal urethral caliber.

urethrotomies or long-term dilation by the patient or urologist to keep the channel open. Inevitably, the fibrosis contracts, leading to difficult self-catheterization, false passage, or acute urinary retention. In such cases, a 3-month period of “urethral rest” via suprapubic urinary diversion is advised before open reconstruction (Terlecki et al, 2011).

Surgical Reconstruction. Open posterior urethroplasty through a perineal anastomotic approach is the treatment of choice for most urethral distraction injuries because it definitively cures the patient without the need for multiple procedures. When preoperative studies have determined that the prostatic urethral apex can be reached by a perineal approach, the patient is placed in the high lithotomy position, and a midline or lambda-shaped incision is made. The bulbar urethra is freed and mobilized from the site of urethral rupture to the midsrotum. The scar tissue of the urethral rupture defect is excised, and the prostatic urethra is identified at the apex of the prostate. Care must be taken to excise carefully and meticulously all fibrotic tissue from the proximal urethral margin until at least a 28-Fr bougie passes without resistance (Fig. 101-23 on the Expert Consult website) (Turner-Warwick, 1989; Morey and McAninch, 1997). The bulbar urethra is then anastomosed in a tension-free manner to the prostatic urethra.

In 95% of patients, posterior urethral anastomosis is successfully achieved through a perineal approach alone (Carr and Webster, 1997). Adjunctive maneuvers such as corporeal separation, inferior pubectomy, and corporeal rerouting have been routinely implemented if direct anastomosis proves difficult (Mundy, 1997; Flynn et al, 2003). Others have found these maneuvers, especially suprapubic rerouting, to be unnecessary and/or unhelpful (Morey and McAninch, 1997; Rosenstein and Jordan, 2003; Cooperberg et al, 2007; Kizer et al, 2007).

Total removal of the symphysis pubis, first reported by Pierce in 1962 (Pierce, 1962), has been recommended when severe injuries result in complicating features such as fistula or marked displacement or retropubic fixation of the prostate (Netto, 1985; McAninch, 1989; Asci et al, 1999). Alternatively, a combined abdominoperineal approach (with or without partial pubectomy) has proved helpful in cases of severe fibrosis, fistula, previous failed anastomotic urethroplasty, and associated bladder neck injury and in pediatric cases (Waterhouse, 1976; Al-Rifaei et al, 1991; Koraitim, 2003, 2005; Pratap et al, 2006). It is important to limit the lithotomy time to 5 hours or less to prevent lower extremity complications (Anema et al, 2000) when any complex urethral reconstruction is undertaken.

Complications

Erectile Dysfunction. Some degree of impotence is noted in 82% of patients with pelvic fracture and urethral distraction injury (Flynn et al, 2003), although the average reported rate is approximately 50% (Corriere et al, 1994; Routt et al, 1996; Elliott and Barrett, 1997; Asci et al, 1999; Koraitim, 2005). The etiology is multifactorial and variably attributed to cavernous nerve injury, arterial insufficiency, venous leak, and direct corporeal injury (Narumi et al, 1993; Munarriz et al, 1995; Shenfeld et al, 2003). Factors that correspond to the severity of the injury, such as diastasis of the pubic symphysis, lateral displacement of the urethra, and long urethral gap, have been found to correlate with erectile dysfunction (Koraitim, 2013).

Some surgical series have shown a small number of patients with new-onset or worsened erectile dysfunction after reconstruction (Tunc et al, 2000); however, the complications of the original pelvic injury are difficult to differentiate from the complications of attempts to repair urethral and bladder injuries. Accounts of greater risk of erectile dysfunction and incontinence with primary realignment were published before the advent of flexible endoscopes (Koraitim et al, 1996). Several studies have shown that patients treated with modern techniques of primary endoscopic realignment have rates of impotence and incontinence similar to those of patients who have had either no treatment or delayed open reconstruction (Kotkin and Koch, 1996; Asci et al, 1999; Koraitim, 2005;

Mouraviev et al, 2005). These studies support the conclusion that these complications are usually the result of the injury itself and not of the treatment (Follis et al, 1992; Elliott and Barrett, 1997; Porter et al, 1997; Corriere, 2001). Some patients who become impotent after injury spontaneously recover erectile function 1 or 2 years later (Turner-Warwick, 1989; Morey and McAninch, 1997; Koraitim, 2005).

Many patients who become impotent as a result of pelvic fracture have some degree of arterial insufficiency (Armenakas et al, 1993; Matthews et al, 1995). Because patients with impotence may be more vulnerable to restenosis after posterior urethroplasty as a result of bulbar urethral ischemia, some experts have suggested that “at-risk” patients undergo preoperative penile arterial duplex Doppler studies to identify candidates suitable for initial penile revascularization (Matthews et al, 1995; Rosenstein and Jordan, 2003). However, indications for penile revascularization as a treatment for post-traumatic erectile dysfunction are extremely limited (Kawanishi et al, 2004). Overall rates of incontinence, anejaculation, and areflexic bladder are low (2% to 4%) (Corriere et al, 1994; Elliott and Barrett, 1997; Asci et al, 1999; Anger et al, 2008), and these conditions tend to be secondary to the original injury.

Recurrent Stenosis. After posterior urethroplasty, 5% to 15% of patients have recurrent stenosis at the anastomosis (Mundy, 1996; Flynn et al, 2003; Koraitim 2005; Cooperberg et al, 2007). Endoscopic treatment (e.g., with direct-vision internal urethrotomy) is often successful in this setting because most fibrotic tissue has been eliminated (Netto et al, 1989; Koraitim 2003).

Incontinence. Urinary continence after urethral distraction is the rule rather than the exception, despite destruction of the external sphincter from either the injury itself or the subsequent repair. Incontinence rates after reconstruction are low—less than 4% (Koraitim, 2005). The mechanism of continence is thought to be largely attributable to bladder neck function (Iselin and Webster, 1999). Urodynamic data show that a significant proportion of patients also have identifiable distal rhabdosphincteric function (Whitson et al, 2008).

Anterior Urethral Injuries

In contrast to posterior urethral distraction, anterior injuries are most often isolated (Kiracofe et al, 1975). Most occur after straddle injury and involve the bulbar urethra, which is susceptible to compressive injury because of its fixed location beneath the pubis. A smaller percentage of injuries to the anterior urethra are the result of direct penetrating injury to the penis.

As with posterior urethral injury, a high index of suspicion must be maintained in all patients with blunt or penetrating trauma in the urogenital region, and urethrography should be performed in any case of suspected urethral injury (Husmann et al, 1993). Clinical signs of anterior urethral injuries include blood at the meatus, perineal hematoma, gross hematuria, and urinary retention. In severe trauma, Buck fascia may be disrupted, resulting in blood and urinary extravasation into the scrotum (Fig. 101-24 on the Expert Consult website). The primary morbidity of straddle injury is urethral stricture, which may become symptomatic years later (Park and McAninch, 2004).

Initial Management

Armenakas and McAninch (1996) proposed a simple, practical classification scheme dividing anterior urethral injuries on the basis of radiographic findings into contusion, incomplete disruption, and complete disruption. Contusions and incomplete injuries can be treated with urethral catheter diversion alone. Initial suprapubic cystostomy is the standard of care for major straddle injuries involving the urethra (Park and McAninch, 2004); however, primary anterior urethral realignment has shown promising results with respect to stricture rate and erectile dysfunction in patients with straddle injuries of lesser magnitude (Ying-Hao et al, 2000; Yu et al, 2007).

Figure 101-23. Intraoperative view of normal membranous urethra after fibrotic tissue was excised during perineal bulbomembranous urethroplasty.

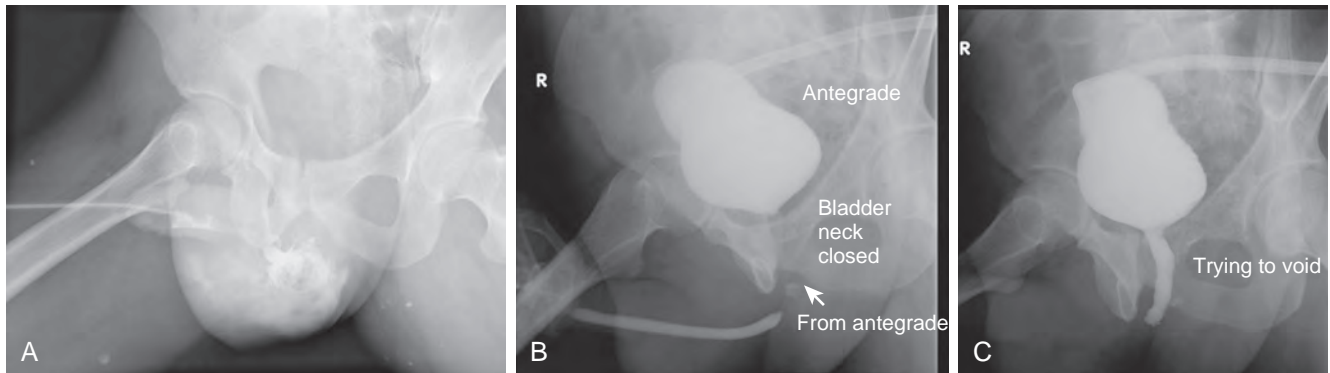

Figure 101-24. A, Extravasation of contrast medium seen in the scrotum on a retrograde urethrogram in a patient with a straddle injury. B, Retrograde and antegrade urethrograms show distal limit of urethral patency, but the bladder neck does not open. C, Repeat antegrade urogram study showing proximal limit of urethral patency.

Primary surgical repair is recommended for low-velocity urethral gunshot injuries (Kunkle et al, 2008); catheter alignment alone is associated with a far worse stricture rate (Husmann et al, 1993). Debridement of the corpus spongiosum after trauma should be limited because corporeal blood supply is usually robust, enabling spontaneous healing of most contused areas (Kiracofe et al, 1975; Husmann et al, 1993). Initial suprapubic urinary diversion is recommended after high-velocity gunshot wounds to the urethra, followed by delayed reconstruction.

Delayed Reconstruction

Before any planned procedure, a retrograde urethrogram and voiding cystourethrogram should be obtained to define the site and length of the obliterated urethra clearly. Urethral ultrasound examination may help delineate the length and severity of stricture. Retrograde injection of saline combined with antegrade bladder filling fills the urethra proximally and distally, and a 10-MHz sonogram clearly defines the nondistensible segment to be excised. Dense fibrous tissue from trauma often demonstrates a fixed, nondistensible appearance sonographically with significant shadowing (Morey and McAninch, 2000). Ultrasound imaging of urethral strictures may be more accurate than retrograde urethrography (Mitterberger et al, 2007), although it is highly operator dependent and not widely used at the present time.

Anastomotic urethroplasty is the procedure of choice in the totally obliterated bulbar urethra after a straddle injury. The typical scar is 1.5 to 2 cm long and can readily be completely excised. The proximal and distal urethra can be mobilized for a tension-free, end-to-end anastomosis. This is a highly successful procedure in more than 95% of cases (Santucci et al, 2002; Jordan et al, 2010).

Endoscopic incision through the scar tissue of an obliterated urethra is a hopeless procedure doomed to failure. Partial urethral narrowing can initially be treated by endoscopic incision or dilation with greater success. Repeated endoscopic manipulation is neither clinically effective nor cost-effective for the treatment of urethral strictures (Greenwell et al, 2004). Patients who undergo repeated endoscopic procedures are also more likely to require complex reconstructive procedures such as grafts (Park and McAninch, 2004; Hudak et al, 2012). Open repair should be delayed for several weeks after instrumentation to allow the urethra to stabilize, and a 2-month period of suprapubic urinary diversion may be prudent preoperatively to optimize conditions for repair of complex or recurrent strictures that have been catheter dependent (Terlecki et al, 2011). Finally, UroLume stents are contraindicated in the setting of traumatic urethral strictures (Wilson et al, 2002).

KEY POINTS: LOWER GENITOURINARY TRACT INJURIES

- Although most bladder injuries are associated with pelvic fractures, only 10% of patients with pelvic fracture have bladder injuries.
- Intraperitoneal bladder injury from external trauma requires urgent operative repair.
- Prompt suprapubic catheter drainage is recommended for initial management of pelvic fracture urethral disruption injury; although primary realignment may be performed in stable patients, close follow-up is essential because of the high rate of stricture formation.
- Posterior urethroplasty by excision and primary anastomosis is the treatment of choice for urethral distraction injuries, although a single attempt at endoscopic treatment may be reasonable for short stenoses.

Endocrine Control of Prostate Growth

Regulation of Prostate Growth by Steroids and Protein Growth Factors

Regulation of Prostate Growth at the Molecular Level: Steroid Receptors

Prostatic Secretions and Proteins

Coagulation and Liquefaction of Semen

Prostate Secretions and Drug Transport

The focus of this chapter is on the development, anatomy, histology, and physiology of the prostate and seminal vesicles, the male sex accessory glands that contribute to seminal fluid. A general and molecular knowledge regarding the formation and physiologic function of the prostate is becoming increasingly important because reactivation or recapitulation of developmental processes appears to occur during pathologic processes such as benign prostatic hyperplasia (BPH) and the development of aggressive prostate cancer (Marker, 2008; Schaeffer et al, 2008; Pritchard et al, 2009). In addition, the physiologic processing of prostate-specific antigen (PSA) and other cellular constituents of the prostate has begun to play increasingly important roles in the development of clinical prostate biomarkers (Mikolajczyk et al, 2004; Vickers et al, 2011; Loeb and Catalona, 2014).

DEVELOPMENTAL AND CELL BIOLOGY

Prostate

Regional Differentiation of the Lower Urinary Tract

The prostate is a derivative of the primitive endoderm (gut tube). Regional differentiation of the primitive gut tube into foregut, midgut, and hindgut is followed by a swelling at the caudal end that creates the cloaca. The *cloaca*, a Latin term meaning “sewer,” receives output from both the urinary and intestinal tracts and represents the fully differentiated state in birds, reptiles, amphibians, marsupials, and monotremes. In placental mammals, however, the cloaca is divided by the urorectal septum during embryogenesis to create separate urinary and digestive outlets. The ventral urinary compartment is called the *primitive urogenital sinus*, which further segments into the urinary bladder at its cranial end and the urethra at its caudal terminus.

Prostate Budding

In males, the prostate develops just caudal to the bladder neck via the proliferation of epithelial buds extending out from the urogenital sinus epithelium. Prostate buds invade at stereotyped locations that pattern the future development of distinct prostate

lobes in the rodent and, potentially, zones in the human. These regions prepare for epithelial bud invasion by “mesenchymal condensation,” a process in which urogenital sinus mesenchymal cells (cells constituting loose connective tissue that will differentiate into stromal elements) become closely packed together (reviewed in Thomson, 2008). This condensation occurs in both males and females and is therefore androgen *independent*. In contrast, epithelial budding is strictly androgen *dependent* and represents the first events in prostate development that are identifiable at the light microscopic level. Prostate budding requires intricate epithelial-mesenchymal interactions (Fig. 102-1). In humans, prostate budding occurs during the 10th week of gestation. In mice, prostate budding occurs on the 17th day of gestation, 2 days before birth. It is important to note that androgen exposure is not only *necessary* but also *sufficient* to drive prostatic differentiation and growth in the embryo. This fact, along with the ability to easily manipulate androgen levels in experimental animals, makes the prostate a particularly appealing subject for the study of epithelial cell fate determination (Cunha et al, 1987; Schaeffer et al, 2008). Prostate buds initially grow as solid epithelial cords that subsequently (postnatal days 1 to 14 in mice) branch and canalize (Sugimura et al, 1986) as part of a sophisticated branching morphogenesis program.

Cytodifferentiation

In the mouse, the urogenital sinus epithelium begins as a homogeneous cell compartment that differentiates (after birth in mice) into distinct basal (adjacent to stroma) and luminal layers (Wang et al, 2001). Intervening epithelial cells, called *intermediate cells*, are present that have features of both basal and luminal cells. A fourth cell type, the neuroendocrine cell, is present in large numbers before prostate epithelial budding and decreases during embryonic development (Aumuller et al, 2001). The development of this cell type during mouse embryogenesis has not been well characterized, and the source of these cells has been variously proposed to be neural crest or urogenital sinus endoderm (Aumuller et al, 2001; Goldstein et al, 2008), illustrating the need to further delineate lineage commitment events in prostate epithelium.

Figure 102-1. Stromal-epithelial interactions. Shown is a schematic of the types of stromal-epithelial interactions in information transfer and regulation within the prostate. Testosterone and growth factors interact on and between stromal and epithelial cells. The production of growth factors is either stimulated or inhibited by androgens. The growth factors can function on the same cell (autocrine) or on distant cells (paracrine). Nitric oxide (NO) is formed from nerve cells, endothelial cells, or macrophages and affects smooth muscle contraction (see text for details). Important features in this schematic are (1) three types of prostate epithelial cells—neuroendocrine, secretory, and basal; (2) five important prostatic stromal cells—smooth muscle, fibroblast, immune cells, endothelial cells, and nerve cells; (3) testosterone converted to dihydrotestosterone (DHT) by 5 α -reductase in the stromal compartment; (4) three sources of NO production in the prostate—nerve, immune cells (e.g., macrophages), and endothelial cells; and (5) stromal-epithelial interactions mediated through various growth factors (see text). BFGF, basic fibroblast growth factor; ECM, extracellular matrix; EGF, epidermal growth factor; FGF, fibroblast growth factor; IGF, insulin-like growth factor; IGFBP, insulin-like growth factor binding protein; KGF, keratinocyte growth factor; PSA, prostate-specific antigen; T, testosterone; TGF, transforming growth factor; TSH, thyroid-stimulating hormone.

Molecular Features of Prostate Development

Induction of Prostate Budding. Although androgen receptor (AR) signaling through dihydrotestosterone (DHT) is the primary motivating force behind prostate development, it specifies only the timing of events, not their location. The AR signaling machinery is present diffusely throughout the lower genitourinary tract (Takeda et al, 1985; Berman et al, 1995). Prostate epithelial buds form at precise locations through mechanisms that are not understood. This spatial control may involve paralogous homeobox (*Hox*) genes, which are transcriptional regulators that govern differential gene expression along the craniocaudal (head to tail) and proximodistal (e.g., shoulder to fingertip) axes in a variety of tissues, including the genitourinary tract (reviewed in Beck et al, 2000; Kmita and Duboule, 2003). In vertebrates, the paralogous *Hox* genes exist as four similar clusters (clusters A, B, C, and D), each of which resides on a separate chromosome and encodes genes whose chromosomal position from 3' to 5' mirrors their expression pattern in the embryo. The paralogous genes are distinct from other, more distantly related transcription factor families that also contain DNA-binding homeobox motifs, such as the NK family, whose members are expressed in a more discrete, organ-specific manner (e.g., see the discussion

of Nkx3.1, later). Paralogous *Hox* genes are sequentially numbered from 1 to 13, with the higher numbers in the 5' position showing the most distal or caudal expression patterns. Accordingly, *Hoxa13*, *Hoxb13*, and *Hoxd13* are *paralogs* on chromosomes 7, 17, and 2, respectively, and have overlapping expression patterns and functions in distal genitourinary tract development. *Hoxb13* regulatory elements have been characterized that restrict its function to the caudal end of the genitourinary and digestive tracts and can be used to engineer androgen-independent prostatic expression of genes of interest (McMullin et al, 2009). Homozygous mutations in individual *Hox* genes result in subtle changes in prostatic branching patterns (Podlasek et al, 1997) and/or defective epithelial maturation (Economides and Capecchi, 2003). Mutations involving more than one of these genes results in significantly more severe urogenital phenotypes, such as significant prostate hypoplasia in *Hoxd13/Hoxb13* compound mutant mice or failure of separate urinary and gastrointestinal tract outlets to form in *Hoxa13/Hoxd13* compound mutants (Kondo et al, 1997; Warot et al, 1997).

Mesenchymal condensation occurs in both males and females, so it is not sufficient to drive prostate development but may be necessary. Condensation of the ventral mesenchymal pad is defective in mice lacking the gene for Noggin (see the section on the

transforming growth factor- β [TGF- β] family, later, for further discussion of the roles of Noggin in prostate development), which antagonizes binding of bone morphogenetic protein (BMP) ligands to their receptors (Cook et al, 2007). This observation suggests that BMP signaling enhances mesenchymal condensation, either by direct action on mesenchyme or through regulation of epithelial-derived factors important in this process. Condensed mesenchyme is highly enriched for expression of fibroblast growth factors (FGFs) that are essential for epithelial bud outgrowth. For example, mice with engineered mutations of the mesenchyme-specific growth factor *Fgf10* gene generate small abortive epithelial buds and fail to grow prostates (Donjacour et al, 2003).

Epithelial Budding. The earliest event seen in the epithelium during prostate development appears to be the upregulation of sex-determining region Y-box 9 (*Sox9*), an androgen-dependent transcription factor, induced via mesenchymal-dependent FGF signaling (Huang et al, 2012). *Sox9* appears to be crucial for the initiation of prostate epithelial lineage. After this, there is increased epithelial expression of the NK homeobox transcription family member *Nkx3.1*. This transcription factor influences the degree of branching in the mature mouse prostate, where it can also act as a tumor suppressor (Bieberich et al, 1996; Bhatia-Gaur et al, 1999; Abate-Shen et al, 2008).

Mutations in the transcriptional regulator p63 (*TP63*) (Signoretto et al, 2000) or in the AR signaling axis (reviewed in Cunha et al, 1987) can also abolish prostate induction. Of note, a striking aspect of the induction of prostate epithelial budding is the finding by Cunha and Lung (1978) that AR signaling is required in the mesenchyme but dispensable in the epithelium. Thus the action of androgens appears to be indirect, leading to the hypothesis that mesenchymal cells secrete inductive factors in response to androgens called *andromedins* (Yan et al, 1992). *TP63* has transcriptional repressor and activator activities that balance differentiation and stem and progenitor cell functions in epithelia (McKeon, 2004). The transcriptional targets of *TP63* in prostate epithelial cells (PrECs) remain to be elucidated (Grisanzio and Signoretti, 2008).

Noggin mutations selectively impair budding of the ventral lobes of the prostate, leaving anterior and dorsolateral budding unimpaired (Cook et al, 2007). Overall, however, the process appears to be a very robust one, with evidence of prostate epithelial bud formation persisting in the presence of a variety of genetic mutations that affect future steps in prostate ductal morphogenesis, particularly branching morphogenesis.

Once set in motion, prostate growth and homeostasis continue to require androgens throughout life, and this requirement appears to continue to be indirect, through mesenchymal or stromal AR signaling. Epithelial branching morphogenesis occurs through signaling cascades that inhibit further outgrowth along the long axis of an extending epithelial bud while stimulating lateral growth at its tip (Hogan, 1999). Through engineered deletion of genes in transgenic mice, several individual genes and components of classic morphogenetic pathways have been shown to be required for branching morphogenesis. Indeed, morphologic aberrations seen on interruption of a cellular pathway may be the most sensitive measure of a role for that pathway in regulation of prostate growth. Accordingly, a wide variety of genes and pathways have been strongly implicated in prostate branching morphogenesis, only a few of which are covered here. For a more comprehensive perspective, including additional pathways such as those centered around Notch and Forkhead proteins, the reader is referred to recent reviews (Leong and Gao, 2008; Matusik et al, 2008).

Nkx3.1 and Sox9. *Nkx3.1* helps determine the branching pattern of the prostate, as demonstrated by the reduced numbers of duct tips seen in mice with engineered *Nkx3.1* deletion (Bhatia-Gaur et al, 1999). This relatively subtle phenotypic change may be important, however, as indicated by a dramatic decrease in the ability of *Nkx3.1*-mutant prostates to manufacture mature secretory proteins (Bhatia-Gaur et al, 1999). In addition to its role in the initiation of prostate development, *Sox9* appears required for bud growth and branching as well as ductal outgrowth (Thomsen et al, 2008).

Fibroblast Growth Factors. The FGF family of related secreted peptides promotes growth in recipient cells by binding to cell surface receptors and activating intracellular second-messenger cascades. Epithelial branching morphogenesis, be it in the lung, salivary gland, mammary gland, or prostate, requires such signals to proceed. Of the FGFs, *Fgf-7* (keratinocyte growth factor) and *Fgf-10* have been studied most extensively in prostate development. Both of these ligands preferentially bind to *Fgfr-2* over the three other family members (*Fgfr-1*, *Fgfr-3*, and *Fgfr-4*) (reviewed in Thomson, 2001, 2008). Ligand binding activates the intracellular microtubule-associated protein kinase (MAPK) pathway, leading to enhanced activity of growth-promoting transcription factors and increased proliferation.

Fgfr-2 is expressed on developing PrECs, where it can interact with its coreceptor *Frs-2 α* . *Fgf-7* and *Fgf-10*, in contrast, are secreted by prostate mesenchyme. This arrangement, along with androgen-independent growth of prostate organ cultures exposed to these ligands, has led to the proposal that they act as andromedins (Yan et al, 1992; Lu et al, 1999). Accordingly, *Fgf-10*-deficient mice have almost complete failure of prostate development, and mice lacking *Fgfr-2* or *Frs-2 α* demonstrate prostate hypoplasia and decreased epithelial branching (Donjacour et al, 2003).

Hedgehog Signaling Pathway. Across a variety of organs, elaboration of secreted hedgehog (Hh) ligands (Sonic hedgehog, Indian hedgehog, and Desert hedgehog) by epithelial cells and reception in adjacent mesenchyme coordinate the activities of the Gli family proteins in regulating hedgehog pathway target genes. In the mesenchyme of developing prostate, several Hh target genes have been identified (Yu et al, 2009), including the cytokine *Cxcl14*, the insulin-like growth factor-binding protein *Igfbp3*, and the delta/notch-like epidermal growth factor-related receptor *Dner*. The roles of these particular genes in prostate development have yet to be ascertained, but, as a whole, Hh pathway target genes have been implicated in placement of prostate epithelial buds and in subsequent ductal branching and outgrowth. In particular, buds form in the absence of the dominant Hh ligand in the prostate (Berman et al, 2004) but are mislocalized in prostates of mice bearing mutations of downstream effectors of the pathway, Gli proteins (Doles et al, 2006). Later in development, Hh ligands enhance epithelial outgrowth and branching (Freestone et al, 2003), which proceed abnormally in prostate organ cultures treated with Hh pathway antagonists (Lamm et al, 2002; Freestone et al, 2003; Berman et al, 2004). In adult animals the pathway may play a role in homeostasis, as indicated in a failure of prostates to regenerate after castration of animals treated with antibodies or small molecules that block Hh signaling (Berman et al, 2004). Taken together, these data indicate a growth-promoting role for the pathway in prostate epithelium, one that may have clinical relevance in pathologic prostate growth (reviewed in Shaw and Bushman, 2007).

Transforming Growth Factor- β Superfamily. TGF- β superfamily members include TGF- β itself, as well as growth and differentiation factors (GDFs) and BMPs. These factors act through transmembrane receptors and the SMAD family of intracellular signal transducing proteins (Schmierer and Hill, 2007). Little is known about GDFs in the prostate, but both TGFs and BMPs are likely to play important roles. In organogenesis this superfamily is best known as a mesenchymal mediator of epithelial growth suppression, but (less frequently) they can also stimulate growth and/or be produced by epithelial cells. TGF- β 1 inhibits net growth of the prostate but can stimulate growth in certain regions of the gland, particularly in the distal tips of the ventral prostate (Tomlinson et al, 2004a). Although the mechanism for growth promotion by TGF- β 1 is unclear, the growth suppressive effect could quite reasonably relate to its ability to suppress levels of another mesenchymal growth factor, FGF-10 (Tomlinson et al, 2004b) (see FGF section, earlier). A similar mechanism could remain in place in mature males, in whom TGF- β signaling in proximal ducts is believed to help to maintain prostate epithelial stem cells in a quiescent (growth-suppressed) state (Salm et al, 2005). BMP-4 and BMP-7 exert important and highly localized growth-suppressive activities in prostate development that help guide branching morphogenesis and prevent overproduction and

TABLE 102-1 Summary of the Anatomy and Cell Biology of the Prostate Gland

COMPONENTS	PROPERTIES
DEVELOPMENT	
Seminal vesicles	From wolffian ducts through testosterone stimulation
Prostate	From urogenital sinus through dihydrotestosterone stimulation
PROSTATE ZONES	
Anterior fibromuscular	30% of prostate mass, no glandular elements, smooth muscle
Peripheral	Largest zone, 75% of prostate glandular elements, site of carcinomas
Central	25% of prostate glandular elements; surrounds ejaculatory ducts
Transitional	Smallest zone, surrounds upper urethra complex, sphincter
	5% of prostate glandular elements, site of benign prostatic hyperplasia
	15%-30% of prostate volume
EPITHELIAL CELLS	
Basal	Small and flattened undifferentiated, nonsecretory cells with a low proliferative index (<1%) that express keratins 5, 14, and 18
Intermediate	Proliferating cell type that has characteristics intermediate between basal and secretory cells, including production of basal and secretory cell keratins
Columnar secretory	Terminally differentiated, nondividing, rich in acid phosphatase and prostate-specific antigen; 20 μ m tall, most abundant cell, keratins 5 and 18
Neuroendocrine	Terminally differentiated, nonproliferating cells that express serotonin, chromogranin-A, neuron-specific enolase, and synaptophysin proteins
STROMAL CELLS	
Smooth muscle	Rich in α -actin, myosin, and desmin
Fibroblast	Vimentin rich and associated with fibronectin
Endothelial	Associated with fibronectin; alkaline phosphatase positive
TISSUE MATRIX	
Extracellular matrix	
Basement membrane	Type IV and V collagen meshwork that is laminin rich and supports basal cells, stem cells, transit-amplifying cells, and secretory epithelium
Connective tissue	Type I and type III fibrillar collagen; elastin
Glycosaminoglycans	Sulfates of dermatan, chondroitin, and heparin; hyaluronic acid
Cytoplasmic	Tubulin, α -actin, and intermediate filaments of keratin
Nuclear matrix	Dynamic structure of the nucleus that directs the functional organization of DNA into loop domains; contains ribonuclear proteins

disorganized epithelial growth. Like TGF- β , BMPs are most active during epithelial budding and subsequent prostate branching (Lamm et al, 2001; Tomlinson et al, 2004a; Grishina et al, 2005) (embryonic day 17 through postnatal day 5 in the mouse). Activation of BMP signaling suppresses branching morphogenesis, as indicated by experimental addition of exogenous BMP-4 or BMP-7 protein to prostate organ cultures (Lamm et al, 2002; Grishina et al, 2005) or by genetic deletion of the BMP inhibitor Noggin (Cook et al, 2007). BMP inactivation can show the opposite effect, as epithelial overgrowth of prostates with genetic deletion of BMP-7 (Grishina et al, 2005).

Prostate Zonal and Lobar Anatomy. The rodent prostate is divided into paired anterior, dorsolateral, and ventral lobes. Each empties into the urethra separately at its proximal extreme, with the distal end floating freely in the pelvic cavity. In contrast, the human prostate, like that of most primates and canine species, grows as a single organ encircling the urethra. The individual prostate zones, however, have distinct architectural and molecular features and have a propensity to develop distinct pathologies (Table 102-1). For instance, the transitional zone surrounding the urethra has the propensity to undergo BPH, making males vulnerable to urinary obstruction, whereas the peripheral zone, which contains the majority of the glandular elements of the prostate, is the most

common site for prostate cancer. In rodents, the anterior, ventral, and dorsolateral lobes are named for the distinct locations of the urethra from which they originate. Each lobe also has a different branching pattern with a distinctive histologic appearance. These differences, reviewed by Timms (2008), have been likened to different zones of the human prostate histologically (Price, 1963), molecularly (Berquin et al, 2005; Thielen et al, 2007), and in terms of propensity to be affected by disease (the dorsolateral prostate, for instance, is most similar to the human peripheral zone). In mice, mRNA transcripts for spermine-binding protein, probasin, and renin-1 are specific for ventral, dorsolateral, and anterior lobes, respectively (Cook et al, 2007), whereas human zone-specific gene expression has not been as well characterized.

Although the gene expression patterns of individual human prostate zones have not been extensively studied, there have been efforts to characterize the zonal distribution of prostate-secreted proteins, in particular of PSA, at least in the adult prostate. For instance, Mikolajczyk and colleagues described BPSA (BPH-related PSA) as a form of unbound PSA that is increased in the transition zone of the prostate (Mikolajczyk et al, 2000a). In contrast, the proPSA zymogen (a precursor of PSA) has been found to be preferentially detected in the peripheral zone (Mikolajczyk et al, 2000b).

Figure 102-2. Hypothetical cell differentiation in adult prostate. Basal cells (*medium blue*) express basal cell proteins, including cytokeratin (CK) proteins 5 and 14, p63, CD49f, and Sca1. Stem cells within the basal cell compartment (*dark blue*) express basal cell proteins, as well as Tacstd2 and c-kit. Basal stem cells populate the basal cell compartment (*medium blue*) and eventually intermediate cells (*light blue*). Intermediate cells proliferate and differentiate into quiescent luminal cells (*orange*). Neuroendocrine cells (*purple*) are also believed to derive from epithelial stem cells. Formal lineage tracing has not been performed in all of these cell types; thus the true differentiation pathway remains to be determined. (Modified from Wang Y, Hayward S, Cao M, et al. Cell differentiation lineage in the prostate. *Differentiation* 2001; 68[4-5]:270–9.)

KEY POINTS: EMBRYONIC DEVELOPMENT

- The wolffian ducts develop into the seminal vesicles, epididymis, vas deferens, ampulla, and ejaculatory duct. The developmental growth of this group of glands is stimulated by fetal testosterone and not DHT.
- Through tissue recombination experiments in mice and rats, the developing urogenital sinus mesenchyme and epithelium have been shown to partner in prostate development. That is, the development, growth, and function of the male and female urogenital tract require stromal-epithelial interaction and action of steroid sex hormones. Androgen acts on the mesenchyme to indirectly induce prostate epithelial outgrowth during development and homeostasis in adulthood.

Prostate Cell Types

The prostatic epithelium in the human is composed of two major cellular compartments: epithelial cells and stromal cells (see Table 102-1). The prostate epithelial compartment consists of basal epithelial cells, intermediate cells, neuroendocrine cells, and luminal secretory epithelial cells (reviewed by De Marzo et al, 1998a). The stromal compartment architecturally serves as structural support and consists predominantly of connective tissue, smooth muscle cells, and fibroblasts. Most prostate cell types have been characterized *in vitro* (Peehl, 2005).

In most glands with renewing cell populations, there is a steady-state flow of cells from mostly quiescent stem cells to a more rapidly dividing pool of transient proliferating cells. This proliferating population finally reaches terminal differentiation, characterized by metabolically active secretory epithelium. In the prostate, cell lineage has not been rigorously determined but has been inferred from a variety of sources. A hypothetical differentiation scheme for prostate epithelium is presented in Figure 102-2. As in most multi-layered epithelia, stem cells reside in the basal compartment and appear to give rise to all of the other epithelial cell types, as well as neuroendocrine cells. These include fully differentiated secretory cells that line glandular lumens (luminal cells), neuroendocrine

cells that secrete bioactive peptides, and intermediate cells that show phenotypic features that are intermediate between basal cells and luminal cells.

Luminal Epithelial Cells

The luminal epithelial cell is the “workhorse” of the prostate gland, responsible for epithelial barrier integrity and production of prostatic secretion. Luminal cells constitute most of the prostate epithelium. These tall (10 to 20 μm) columnar secretory epithelial cells are terminally differentiated and have a low proliferative index (De Marzo et al, 1998a); they are easily distinguished by their morphologic features and abundant secretory granules and enzymes. Secretory cells produce a variety of proteins that characterize prostatic differentiation, including PSA, acid phosphatase, AR, leucine amino peptidase, and 15-lipoxygenase-2 (Shappell et al, 1999; Bhatia et al, 2003). They are also rich in keratin filaments (subtypes 8 and 18) (van Leenders and Schalken, 2003). Secretory cells appear in rows like a picket fence with each cell connected to the next by cell adhesion molecules (CAMs); the apical aspect of these cells projects into the lumen, with the base attached to a basement membrane through integrin receptors (Knox et al, 1994). The nucleus is at the base just below a clear zone (2 to 8 μm) of abundant Golgi apparatus, and the upper cellular periphery is rich in secretory granules and enzymes. The apical plasma membrane facing the lumen possesses microvilli, and secretions move into the open collecting spaces of the acinus. These epithelial cells ring the periphery of the acinus and produce secretions into the acini that drain into ducts connected to the urethra.

Basal Cells

Basal cells (reviewed by De Marzo et al, 1998a) are the smallest of epithelial cells. They have a low mitotic index and are a minor population, accounting for less than 10% of the total cell number. Basal cells express a distinct keratin subtype profile (subtypes 5 and 14) compared with the columnar epithelial cells (subtypes 8 and 18). These cells are typically pyramid shaped with relatively little cytoplasm and condensed chromatin. Basal cells rest on the basement membrane wedged between the bases of adjacent, tall, columnar epithelial cells. The basal cell compartment has long been

considered the likely source of the epithelial stem cells of the prostate because they are relatively undifferentiated with a low proliferative index (approximately 1%) and almost devoid of secretory products, such as PSA and prostatic acid phosphatase (PAP) (see Fig. 102-2). Indeed, when mice are castrated after implantation with human prostate primary xenografts and then restimulated with testosterone, the basal cell population is highly overrepresented, consistent with the concept that the human basal compartment also contains prostate epithelial stem cells (Huss et al, 2004).

Prostate Epithelial Stem Cells

Recent experimental work in the mouse has provided powerful functional evidence for stem cell populations in the prostate, localizing them to the basal compartment, particularly in the proximal portions of prostatic ducts. These experiments used *in vivo* grafting assays to demonstrate critical stem cell characteristics including the ability of long-lived cells to proliferate indefinitely and to give rise to more differentiated phenotypes. Tsujimura and colleagues demonstrated DNA label-retaining PRECs with long-term proliferative potential that were preferentially localized to the proximal segments of prostatic ducts of adult males (Tsujimura et al, 2002). Further studies have mapped the stem cell properties of proximal duct cells to those expressing the mouse stem cell antigen Sca1, the basal cell integrin α_6 (Itga6 or CD49f), the tumor-associated calcium signal transducer Tacstd2 (also known as *Trop2*), and the stem cell factor receptor c-kit (Burger et al, 2005; Xin et al, 2005; Lawson et al, 2007; Goldstein et al, 2008; Leong and Gao, 2008).

Intermediate Cells

Intermediate cells are so named because they possess phenotypic characteristics intermediate between basal and luminal cells. Similarities of these cells to prostate cancer cells have marked them as hypothetical substrates for neoplastic transformation (Verhagen et al, 1992; De Marzo et al, 1998b), although their susceptibility to carcinogenesis is unknown. These investigators proposed that intermediate cells fulfill a transient amplifying function, providing a short-term amplification function for the long-term proliferative capabilities of basal stem cells. Intermediate cells produce basal cell keratins (5 and 14) and the secretory cell keratins 8 and 18 (De Marzo et al, 1998b; Schalken and van Leenders, 2003). Uzgare and colleagues (2004) reported transient amplifying properties of human intermediate cells in culture: a high proliferative fraction with the ability to proliferate for a limited number of generations. Survival of terminally differentiated secretory luminal cells and proliferation of intermediate cells require androgens potentially acting indirectly through the secretion of androgen-regulated growth factors by the stromal compartment (androgens) (Uzgare et al, 2004).

Neuroendocrine Cells

Neuroendocrine cells are cells that release hormones in response to neural stimulation. In the prostate, neuroendocrine cells reside among the more abundant secretory epithelial cells in the normal prostate gland as well as in the urothelium of the prostatic urethra (Aumuller et al, 2001). There are two types of neuroendocrine cells: the first is open and possesses specialized microvilli that protrude into the lumen; the second is closed with long dendrite-like processes that extend to nearby epithelial cells and basal cells close to afferent and efferent nerves (diSant-Agnese and deMesy-Jensen, 1984; diSant-Agnese et al, 1985; Abrahamsson, 1999; Vashchenko and Abrahamsson, 2005).

Thinking on the origin of prostatic neuroendocrine cells has evolved. Aumuller and associates (2001) demonstrated that neuroendocrine cells are readily identified in male and female urogenital sinus epithelium before human prostate development, suggesting that these might represent a separate lineage that is independent of prostate epithelium. More recently, Goldstein and coworkers (2008) showed that neuroendocrine, basal, and secretory luminal cells can

all originate from a common pluripotent *Trop2*-expressing prostate epithelial stem cell precursor.

Current evidence suggests that neuroendocrine cells can influence growth, differentiation, and secretory activity of the prostate epithelium through paracrine and autocrine mechanisms (Abrahamsson, 1999; Vashchenko and Abrahamsson, 2005). Neuroendocrine cells bring about their regulatory activity by the secretion of hormonal polypeptides or biogenic amines such as serotonin. High-pressure liquid chromatography measurements have shown that normal human prostatic tissue contains approximately 1400 ng of serotonin per gram of tissue, and this would certainly emphasize the importance of these cells (Davis, 1987). Higgins and Gosling (1989) have studied the structure and intrinsic innervations of the normal human prostate and have observed acetylcholinesterase-containing nerves associated with smooth muscle in both the peripheral and the central parts of the prostate. In addition, they have shown that the majority of the acini in the peripheral and central regions possess a rich plexus of autonomic nerves and that vasoactive intestinal peptide-positive nerve fibers are found in relation to the epithelial lining acini in the central and peripheral regions of the gland. Lepor and Kuhar (1984) characterized and studied the location of the muscarinic cholinergic receptor in human prostatic tissue and localized it to the epithelial cells. This is consistent with the neuropharmacology of muscarinic cholinergic agonist, which has a marked effect on increasing prostatic secretion. However, the α_1 -adrenergic receptor has its effect in the human prostatic stromal compartment. This is of clinical importance because of the use of selective α_1 -adrenergic antagonists to alleviate bladder outlet obstruction secondary to BPH (Lepor, 1993). Recent work has demonstrated three subtypes of the α_1 -adrenergic receptor (α_{1A} , α_{1B} , and α_{1D}). Of these, the α_{1A} receptor appears to be linked to smooth muscle contraction of the prostate (Lepor et al, 1993).

Neuroendocrine cells are terminally differentiated (i.e., nonproliferating) and do not express detectable AR, PSA, or Bcl-2. These cells release peptide hormones or prohormones by fusion of intracellular granules with the cell membrane and exocytosis of their contents. In addition to serotonin, neuroendocrine cells produce numerous bioactive macromolecules (major examples include bombesin, neuron-specific enolase, calcitonin gene family members, thyroid-stimulating hormone-like peptide, somatostatin, synaptophysin, and parathyroid hormone-like peptide). Neuroendocrine factors appear likely to influence the growth, differentiation, and secretion of epithelium of the prostate in both normal and malignant conditions (Vashchenko and Abrahamsson, 2005).

KEY POINTS: PROSTATE EPITHELIAL CELL TYPES

- The prostatic epithelium in the human is composed of two major cell compartments: epithelial cells and stromal cells.
- The epithelial cell types include mature secretory and terminally differentiated cells, neuroendocrine cells, intermediate cells, and basal cells.
- Prostatic stem cells reside in the basal compartment and are enriched in the proximal portions of prostatic ducts.

Stroma and Tissue Matrix

The noncellular stroma and connective tissue of the prostate make up what is termed the *ground substance* and the *extracellular matrix* in what was first suggested by Arcadi (1954) to play an important role in prostate function and disease. The extracellular matrix has long been recognized as one of the important inductive components during normal development of many different types of cells (Cunha, 1976; Hay, 1981; Bissell et al, 1982; Getzenberg et al, 1990; Risbridger et al, 2005). Classic tissue recombination experiments by Cunha and colleagues (1987) have clearly shown the direct importance of the isolated embryonic mesenchyme to the induction of differentiation of normal prostatic epithelial cells (see earlier discussion).

The epithelial cells rest on the basement lamina or membrane, which is a complex structure containing, in part, collagen types IV and V, glycosaminoglycans, complex polysaccharides, and glycolipids. This layer forms an interface to the stromal compartment that provides structural support for the basal cells and their progeny. It consists of an extracellular matrix, ground substance, and a variety of stromal cells, including the fibroblasts, capillary and lymphatic endothelial cells, smooth muscle cells, neuroendocrine cells, and axons (reviewed in [Taylor and Risbridger, 2008](#)).

The **cytomatrix** (cytoplasmic skeleton) terminates in the center of the cell by direct attachment to the **nuclear matrix**. The prostatic epithelial cell therefore has direct structural linkage via the matrix system from the DNA to the plasma membrane. The cytomatrix then makes direct contact with the basement membrane, extracellular matrix, and ground substance of the stroma. This entire interlocking tissue scaffolding or superstructure is termed the **tissue matrix** and may have dynamic properties in ordering and controlling biologic processes as well as in the transport of secretions from the sex accessory tissues ([Getzenberg et al, 1990](#); [Konety and Getzenberg, 1999](#); [Etienne-Manneville, 2004](#); [Miner and Yurchenco, 2004](#); [Hallmann et al, 2005](#)).

Understanding the biologic components of the tissue matrix system within sex accessory tissues is of paramount importance to understanding its physiology. The laminin proteins are glycoproteins of the extracellular matrix that mediate attachment of cells to the type IV collagen of the basement membrane ([Miner and Yurchenco, 2004](#); [Yurchenco et al, 2004](#); [Hallmann et al, 2005](#)). Laminin is produced by epithelial cells but not by fibroblasts; it is a large molecule (approximately 800 kD) with molecular domains that interact with the type IV collagen of the basement membrane and with integrin-type receptors within the cell surface glycocalyx of the epithelial cell ([Aumailley et al, 2005](#)). Laminins are the major anchor filaments in the basement membranes of epithelial cells that stabilize attachment of hemidesmosomes via $\alpha_6\beta_4$ integrin ([Brar et al, 2003](#); [Miner and Yurchenco, 2004](#)). The key functional properties of the laminins are cell adhesion, proliferation, differentiation, growth, and migration. Laminin surrounds the basement membrane of prostate acinar epithelial cells, capillaries, smooth muscle, and nerve fibers but not lymphatics, lymphocytes, or fibroblasts; the laminin structure and its distribution are disrupted in BPH and higher-grade prostatic intraepithelial neoplasia and higher-grade prostate neoplasms ([Sinha et al, 1989](#); [Brar et al, 2003](#); [Miner and Yurchenco, 2004](#)).

In summary, the development and maintenance of the prostate occurs through androgen-dependent and highly regulated tissue morphogenesis in processes involving epithelial cell differentiation, proliferation, and apoptosis ([Cunha et al, 2004](#)). Communication through numerous extracellular interactions is directed to the intracellular cytoskeleton and then to the nuclear matrix, which ultimately regulates a variety of transcriptional cell functions that control such critical phenotypic qualities as cell size and shape, cell motility, epithelial cell turnover, proliferation, and differentiation ([Getzenberg et al, 1990](#); [Pienta et al, 1993](#); [Miner and Yurchenco, 2004](#)).

Seminal Vesicles and Their Development

The sex accessory tissues include the epididymis, ampullae, seminal vesicles, prostate, Cowper (bulbourethral) gland, and glands of Littre. All of these glands have reproductive roles, but the seminal vesicles work in tandem with the prostate and provide an important counterpoint to its biology and pathologic processes. The seminal vesicles are two saccular glands that pair with the vasa deferentia to form the ejaculatory ducts that empty into the craniodorsal aspects of the prostate. Together with the prostate, the seminal vesicles produce seminal fluid that nurtures, protects, and facilitates sperm transport for mammalian reproduction. The division of labor between the prostate and seminal vesicles is surprisingly variable among species. At one end of the spectrum is the dog, a species in which seminal vesicles are absent and the prostate must therefore carry out the functions that are divided between the two glands in

other species. Most mammals, including humans, rats, and mice, occupy the other end of the spectrum, in which the seminal vesicles produce most of the seminal fluid, with the prostate playing a minor role. In species with both glands, physiologic cooperation between the two glands is also appreciable at the molecular level. For example, the major secretory protein product of the seminal vesicles is semenogelin, a 52-kD protein that serves as a substrate for proteolytic enzymes produced by the prostate, including PSA. Proteolysis of semenogelin yields a variety of peptide byproducts that are believed to serve reproductive and antimicrobial functions in humans ([Curry and Atherton, 1990](#)). In mice and rats, seminal vesicle and prostate products cooperate to coagulate the ejaculate into a firm copulatory plug in the vagina during mating. The plug serves as a temporary barrier to further mating by the female, potentially blocking impregnation by competing males.

Seminal vesicles develop from the mesonephric (wolffian) ducts shortly before the onset of prostate development. Seminal vesicle development is strictly dependent on an intact AR signaling pathway, including the ligand testosterone (reviewed in [Wilson et al, 1981](#)). This requirement contrasts to development of the human prostate (see later), which, in addition to an intact AR pathway, requires conversion of testosterone into the more potent 5α -reduced androgen, DHT ([Andersson et al, 1991](#); [Mahendroo and Russell, 1999](#)).

Thick smooth muscle layers constitute the muscular stroma of the seminal vesicles, which surrounds a short columnar-to-cuboidal epithelium. The epithelium has distinct basal and luminal layers that are notable for unusually variable nuclear size and shape, a feature that is also found in prostate cancer ([Epstein and Netto, 2007](#)). Another notable feature of the epithelium of the seminal vesicles, the almost invariable appearance of gold-colored intracytoplasmic pigment, is usually absent in prostate cancer and helps to clarify any confusion between the two entities. Seminal vesicle pigment is thought to derive from cellular byproducts of nonviable sperm ingested by the seminal vesicle epithelium (spermatophagy).

The seminal vesicles are extremely resistant to disease. Given their proximity, shared functions, and similar endocrine requirements to the prostate, it is striking that diseases of the seminal vesicles in humans are vanishingly rare. In contrast, prostate disease, at least in Western cultures, is a nearly universal rite of passage into old age (see subsequent chapters on BPH and prostate cancer). Accordingly, contrasting gene expression between seminal vesicles and prostate has been used as a strategy to discover the molecular basis of prostate cancer risk ([Thompson et al, 2008](#)).

ENDOCRINE CONTROL OF PROSTATE GROWTH

The prostate, like other sex accessory tissues, is stimulated in its growth, maintenance, and secretory function by the continued presence of certain hormones and growth factors. Foremost among these is testosterone, which is converted within the prostate into the more active androgen DHT. Testosterone is synthesized in the Leydig cells of the testes from pregnenolone by a series of reversible reactions. However, once testosterone is converted by 5α -reductase into DHT or converted by aromatase into estrogens, the process is irreversible: **testosterone can be converted to DHT or estrogens, but estrogens and DHT cannot be converted to testosterone**. Androgens, estrogens, and adrenal steroids are believed to have strong effects on different cells and tissues in the body that can vary with development and age. These vary from embryonic development to puberty and on into adult maintenance and aging. Therefore, androgen ablation or androgen treatments have a wide variety of physiologic effects that merit consideration.

The generalized endocrine physiology of the prostate is depicted in [Figure 102-3](#). The hypothalamus releases a small 10-residue polypeptide (decapeptide) referred to as **luteinizing hormone-releasing hormone (LHRH)**, also called **gonadotropin-releasing hormone (GnRH)**. Under the stimulation of LHRH the pituitary releases luteinizing hormone (LH), which is transported to the testes and acts directly on the Leydig cells to stimulate de novo steroid synthesis and

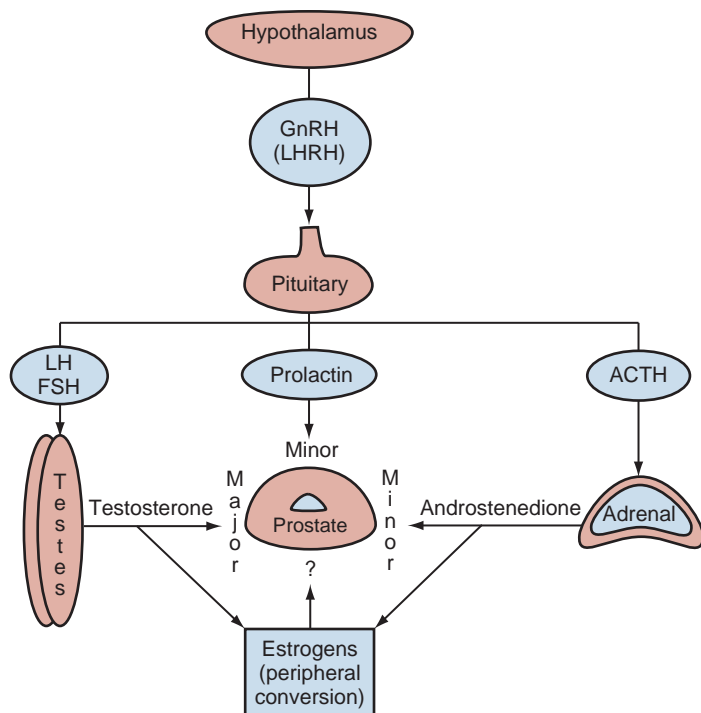

Figure 102-3. Simplified endocrinology of the prostate. Luteinizing hormone–releasing hormone (LHRH), also known as gonadotropin-releasing hormone (GnRH), stimulates the pituitary to release the gonadotropins luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which stimulate the Leydig cells of the testes to synthesize testosterone. Testosterone is the major serum androgen stimulating prostate growth. Peripheral conversion of testosterone by aromatization forms the estrogens in the male. The adrenal gland is under stimulation by adrenocorticotropic hormone (ACTH) and releases the minor androgens, such as androstenedione, which is also converted peripherally to estrogens. Prolactin has also been shown to have a minor effect in stimulating androgen-induced prostate growth. The prostate can produce its own growth factors (autocrine or paracrine) or respond to circulating growth factors.

release of testosterone, the major serum androgen of the body. Most of the estrogen in the male is derived from peripheral conversion of androgens to estrogens through aromatization. Exogenous estrogens, such as diethylstilbestrol, block androgen action not primarily by direct effects on the prostate but indirectly through blocking pituitary function. The estrogen causes a negative feedback on LH release that reduces the serum signal for testicular testosterone production; therefore, estrogen acts as an effective “chemical castration.”

Recent studies in prostate cancer biology have revealed that prostate cancer cells are capable of *de novo* androgen synthesis, leading to renewed interest in steroid 17 α -hydroxylase/17,20-lyase blockade (e.g., abiraterone), or direct AR antagonism (e.g., enzalutamide); however, it is doubtful that benign prostatic epithelial cells produce intracrine androgens in clinically significant amounts, because castration leads to nearly complete involution of the prostate. In addition, the adrenal secretes a weak androgen, androstenedione; however, this also is not a major influence on prostate physiology because castration leads to almost complete involution of the prostate, meaning that insufficient adrenal androgens are present to stimulate any meaningful growth of the normal prostate. Similar to serum testosterone, androstenedione can undergo aromatization to estrone. Overproduction of androstenedione, such as occurs in certain forms of congenital adrenal hyperplasia, may stimulate prostate growth; however, again, the role of normal circulating adrenal androgens in regulating prostate growth is minor. The presence of a nontesticular minor androgen source has led to

the concept of total androgen blockade for the treatment of advanced prostate cancer, whereby both an LHRH agonist and a nonsteroidal antiandrogen are combined to eliminate testosterone production and block any residual androgen stimulation of the prostate from the adrenal gland. With the realization that prostate cancer cells can produce intracrine androgens and various constitutively active AR splice isoforms, true androgen blockade will require further addition of drugs of the newer class such as abiraterone and enzalutamide.

Androgen Production by the Testes

Because the testes produce the major serum androgen supporting prostate and sex accessory tissue growth, it is important to briefly review this function. In the normal human male the major circulating serum androgen is testosterone, which is almost exclusively (approximately 95%) of testicular origin. **Under normal physiologic conditions the Leydig cells of the testis are the major source of the testicular androgens.** The Leydig cells are stimulated by the gonadotropins (primarily LH) to synthesize testosterone from acetate and cholesterol. The spermatic vein concentration of testosterone is 40 to 50 $\mu\text{g/dL}$, approximately 75 times more concentrated than the level detected in the peripheral venous serum (Hammond, 1978), which is approximately 600 ng/dL . Other androgens also leave the testes by the spermatic vein; these include androstenediol, androstenedione (3 $\mu\text{g/dL}$), dehydroepiandrosterone (DHEA) (7 $\mu\text{g/dL}$), and DHT (0.4 $\mu\text{g/dL}$). The concentrations of these androgens are much lower in the spermatic vein than the concentration of testosterone, with all being less than 15% of the concentration of testosterone.

The total testosterone that enters the plasma is referred to as the *testosterone blood production rate* and is 6 to 7 mg/day in the human. Although other steroids, such as androstenedione from the adrenals, can be converted by peripheral metabolism to testosterone, they account for less than 5% of the overall production of plasma testosterone. The plasma half-life of testosterone is only 10 to 20 minutes, which means that a man undergoing bilateral simple orchiectomy is functionally castrated within 1 to 2 hours of surgery. Hence, the most rapid method of androgen suppression for the purposes of immediate relief of spinal cord compression from prostate cancer metastasis is surgical castration.

The average testosterone concentration in the plasma of a man is approximately 611 $\text{ng/dL} \pm 186$, with a normal range of 300 to 1000, which is equal to 10.4 to 34.7 nmol/L in SI units (Table 102-2). Serum testosterone level is not remarkably related to age between 25 and 70 years, although it does decline gradually to approximately 500 ng/dL after 70 years of age. It is recognized that plasma concentrations of testosterone can vary widely in an individual on any one day and may reflect both episodic and diurnal variations in the production rate.

Metabolic androgens such as 17-ketosteroids are then secreted into the urine as water-soluble glucuronide or sulfate conjugates. The total 17-ketosteroid level in the urine in adult men is 4 to 25 mg/24 hr and is not an accurate index of testosterone production, because other steroids from the adrenals as well as nonandrogenic steroids can be metabolized to 17-ketosteroids. Only small amounts (25 to 160 $\mu\text{g/day}$) of testosterone enter the urine without metabolism, and this urinary testosterone represents less than 2% of the daily testosterone production.

Although testosterone is the primary plasma androgen inducing growth of the prostate gland and other sex accessory tissues, it appears to function as a prohormone in that the most active form of the androgen in the prostate is not testosterone but rather DHT (Farnsworth and Brown, 1963; Anderson and Liao, 1968; Bruchovsky and Wilson, 1968) (Fig. 102-4). The formation of DHT involves the reduction of the double bond in the A ring of testosterone through the enzymatic action of the enzyme 5 α -reductase (Fig. 102-5). There are at least two isoforms of this enzyme (type 1 and type 2). Type 2 5 α -reductase expression predominates in human accessory sex tissues and is localized to the fibromuscular stromal compartment (Silver et al, 1994). The type 1 isoform predominates

TABLE 102-2 Average Plasma Levels of Sex Steroids in Healthy Human Males

STERIOD (COMMON NAME)	PLASMA CONCENTRATION (ng/dL)	RELATIVE MOLARITY	DAILY BLOOD PRODUCTION RATE (mg/day)	RELATIVE ANDROGENICITY (RAT VP ASSAY)
Testosterone	611 ± 186	100	6.6 ± 0.5	100
Dihydrotestosterone	56 ± 20	9	0.3 ± 0.06	181
5 α -Androstane-3 α ,17 β -diol (3 β -androstenediol)	14 ± 4	2	0.2 ± 0.03	126
5 α -Androstane-3 β ,17 β -diol (3 β -androstenediol)		<2	<0.3	18
Androstenediol	161 ± 52	26	0.21	
Androsterone	54 ± 32	9	0.28	53
Androstenedione	150 ± 54	25	1.4	39
Dehydroepiandrosterone	501 ± 98	81	29	15
Dehydroepiandrosterone sulfate	135,925 ± 48,000	17,619		<1

17 β -Estradiol	2.5 ± 0.08		0.4	0.75
Estrone		4.6	0.8	0.04

VP, ventral prostate.

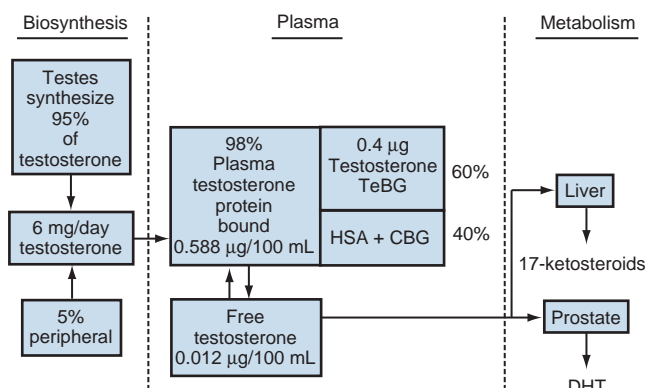

Figure 102-4. Quantitative assessment of the testicular biosynthesis, plasma transport, and metabolism of testosterone. Plasma testosterone is bound to sex steroid-binding globulin (SSBG), human serum albumin (HSA), and cortisol-binding globulin (CBG). All numbers are average values for the normal adult male. DHT, dihydrotestosterone; TeBG, testosterone-binding globulin.

in skin, in prostatic epithelia, and to a lesser extent in prostatic fibromuscular stroma. Inhibition of 5 α -reductase by finasteride appears to be largely selective for the type 2 isoform (Iehle et al, 1995; Habib et al, 1997); the newer agent dutasteride inhibits both type 1 and type 2 5 α -reductase. Both drugs appear to exert similar effects in terms of reduction in prostatic volume and serum PSA concentration, suggesting that the type 2 isoform is the only clinically significant isoform present in the prostate. DHT concentration in the plasma of normal men is low, 56 ± 20 ng/dL, in comparison to testosterone, with a concentration 11-fold higher at approximately 611 ng/dL (see Table 102-2). In summary, although DHT is a potent androgen (2 to 10 times as potent as testosterone in many bioassay systems), its low plasma concentration and tight binding to plasma proteins diminishes its direct importance as a circulating androgen affecting prostate and seminal vesicle growth. In contrast, DHT is of paramount importance within the prostate, where it is formed from testosterone. DHT is the major form of androgen found within the prostate gland (5 ng/g tissue wet weight) and is fivefold higher than testosterone. In the prostate, DHT binds to ARs and activates the receptors to regulate a variety of cellular processes. In summary, DHT becomes the major

androgen regulating the cellular events of growth, differentiation, and secondary functions in the prostate.

The normal adult male plasma levels of some important steroids are summarized in Table 102-2. These values are derived as averages from numerous studies. Individual values can fluctuate with age, time of day, medications, stress, hospitalization, and environmental changes. For this reason, serum measurements of testosterone should be done only in the morning (e.g., 8:00 AM), because late afternoon measurements can drop by as much as 25% by diurnal variation alone (Brambilla et al, 2009).

Adrenal Androgens

There is evidence that overproduction of adrenal steroids can stimulate growth of the prostate gland. For example, in humans, abnormal virilism has been observed in immature males with a hyperfunctioning adrenal cortex. In rodents, overstimulation of the adrenals can also induce limited prostate growth even in the absence of testicular androgens. For example, administration of exogenous adrenocorticotrophic hormone to castrated animals does significantly increase the growth of sex accessory glands (Tullner, 1963; Tisell, 1970; Walsh and Gittes, 1970). However, the effect of normal levels of adrenal androgens on the prostate in noncastrated humans and adult male rats does not appear to be significant because adrenalectomy has little effect on prostate size, DNA, or morphologic characteristics of the sex accessory tissue (Mobbs et al, 1973; Oesterling et al, 1986). Furthermore, after castration in animals, with the adrenals intact, the prostate will finally diminish to a very small size (90% reduction in total cell mass). Finally, the small involuted ventral prostate in the castrated rat cannot be significantly reduced further by additional adrenalectomy or hypophysectomy (Kyprianou and Isaacs, 1987). In castrated rats, the DHT level in the prostatic tissue is approximately 20% that in normal intact animals. Adrenalectomy lowers the DHT to undetectable levels without further diminution in prostate growth. This indicates that a threshold level of DHT is required in the prostate to stimulate growth and that the castrate level is below this threshold. It has also been concluded similarly that the human prostate does not restore itself after castration, indicating that adrenal androgens are insufficient to compensate for the loss of testicular function. Quantitative morphometry of the human prostate (Oesterling et al, 1986) also confirms that the adrenal gland has little effect on the epithelial cell size of the normal prostate.

The adrenal steroid DHEA and the conjugate dehydroepiandrosterone sulfate (DHEAS) as well as androstenedione are androgens

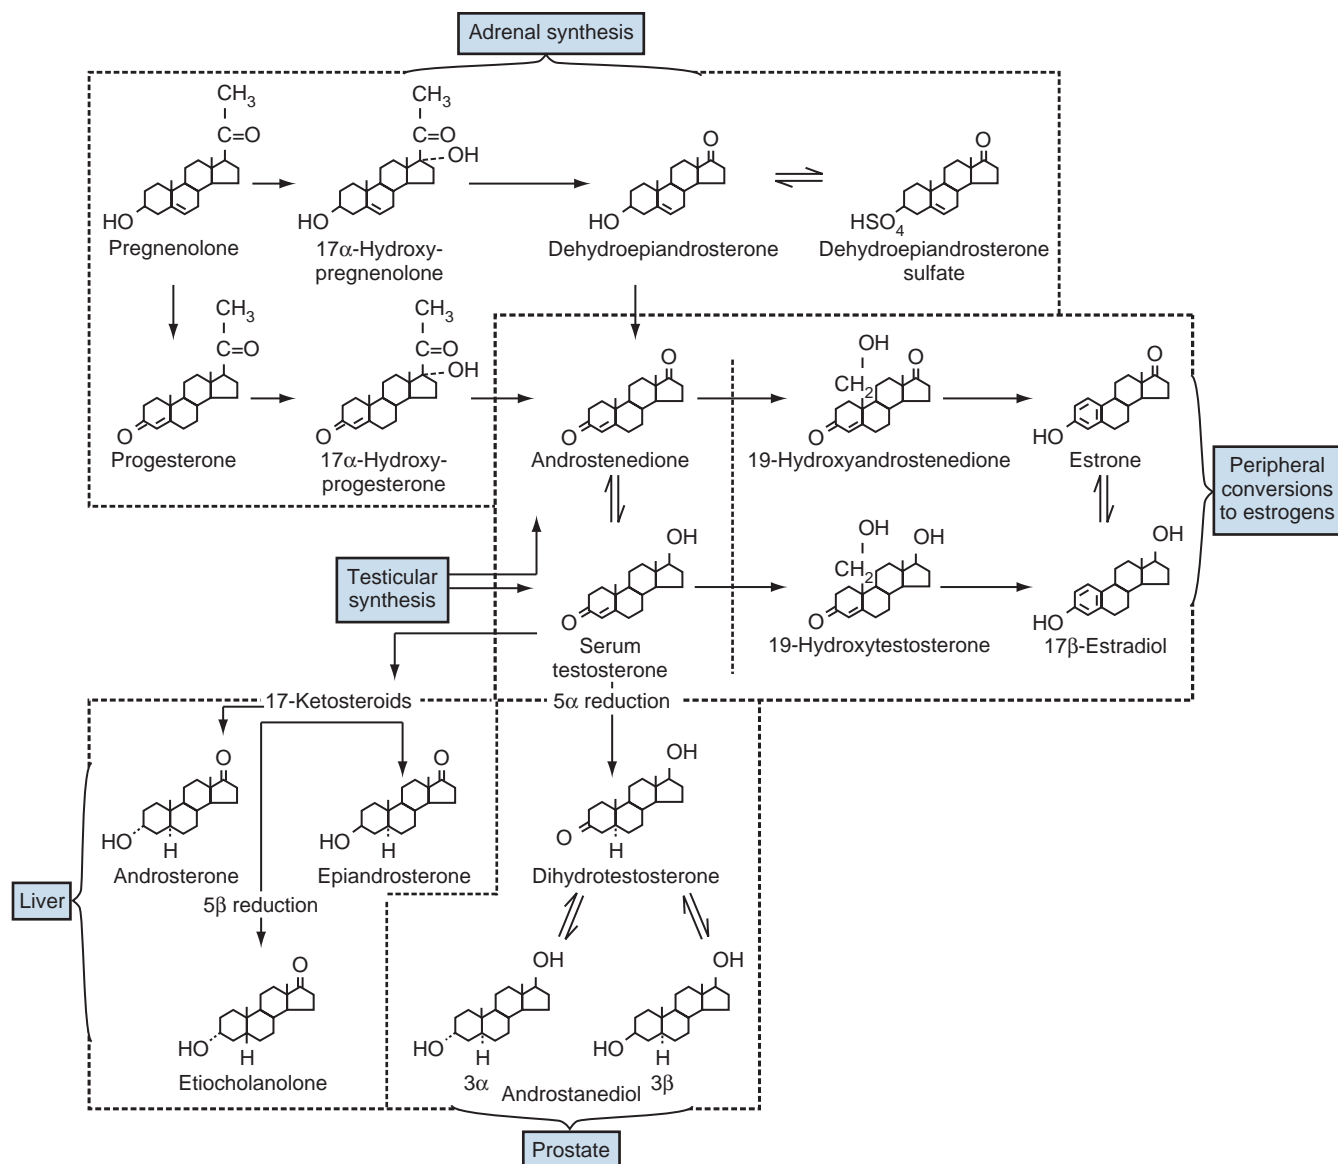

Figure 102-5. Overview of the synthesis and metabolism of testosterone in four main body compartments: adrenal synthesis of androstenedione; peripheral conversion of androgens (androstenedione and testosterone) to estrogens; formation of active androgen (DHT) within the prostate; and inactivation in the liver of testosterone to three types of 17-ketosteroids.

synthesized from acetate and cholesterol (see Fig. 102-5) that are secreted by the normal human adrenal glands. Essentially all of the DHEA in the male plasma is of adrenal cortex origin, and the production rate in males is 10 to 30 mg/day. **Less than 1% of the total testosterone in the plasma is derived from DHEA** (Horton, 1976; MacDonald, 1976). The prostate and seminal vesicles of the rat and the human prostate can slowly hydrolyze DHEAS to free steroids through prostatic sulfatase enzymatic activity, but the degree of conversion is low; hence, DHEAS is not a potent androgen.

A second adrenal androgen is androstenedione, and the plasma concentration in adult men is approximately 150 ± 54 ng/dL (see Table 102-2). The blood production rate of androstenedione in human males is 2 to 6 mg/day, with approximately 20% of the androstenedione being generated by peripheral metabolism of other steroids. **Androstenedione cannot be converted directly to DHT.** An important role for androstenedione in the male may be its peripheral conversion to estrogens through the aromatase reaction (see Fig. 102-5).

The adrenal gland also produces C21 steroids (e.g., progesterone). The plasma production rate at 0.75 mg/day is low, producing

a low plasma progesterone concentration of 30 ng/dL. Although progesterone is weakly androgenic, it does not exert a significant effect on the prostate at the low concentrations present in normal male plasma. **In summary, under normal conditions, the adrenals do not support significant growth of prostatic tissue.**

Estrogens in the Male

The estrogen receptors (ERs) are differentially expressed in the prostate. In the mouse, ER- α is expressed early (1 week) in the stroma of the ventral prostate but by 2 weeks is preferentially expressed in the epithelia, and ER- α is absent altogether in the ventral prostate by 4 weeks. In contrast, ER- β exists in the epithelial compartment as the dominant ER by the fourth week. It is interesting to note, however, that knockout mice for ER (both isoforms) are able to form grossly normal prostates, although fertility may be limited in the ER- α group (Couse et al, 2001). Only small amounts of estrogen are produced directly by the testes. In the plasma of young healthy human males, 75% to 90% of the estrogens are derived from the peripheral conversion of androstenedione and testosterone to

estrone and estradiol through the aromatase reaction (see Fig. 102-5) (Horton, 1976; MacDonald, 1976). The androgenic C19 steroids (testosterone and androstenedione) are converted to the estrogenic C18 steroids first by removal of the 19-methyl group and then by the formation of an aromatic or phenolic steroid A ring (aromatase reaction), present in both estradiol and estrone. Estradiol is formed from testosterone and estrone from androstenedione; these two estrogens are interconvertible. The daily production of estradiol in the human male is 40 to 50 μg , and only 5 to 10 μg (10% to 25%) can be accounted for by direct testicular secretion (see Table 102-2).

Androgen-Binding Proteins in the Plasma

Less than 2% of the total testosterone in human plasma is free or unbound; the remaining 98% is bound to several different types of plasma proteins (see Fig. 102-4). The plasma proteins that bind steroids include human serum albumin, sex hormone-binding globulin (denoted SHBG or SHBG), corticosteroid-binding globulin (also named *transcortin*), progesterone-binding globulin, and, to a lesser extent, α_1 -acid glycoprotein. Under normal conditions, the total amount of testosterone bound to progesterone-binding globulin and α_1 -acid glycoprotein is nominal and is usually ignored. SHBG levels are suppressed by circulating androgens as well as anabolic steroids and may be decreased by diabetes and obesity.

The regulation of the amount of androgen that is free is an important physiologic variable and varies in different species. The total amount of steroid bound depends on two factors: (1) the *affinity* of the steroid to bind to a specific protein and (2) the *capacity*, which is the maximal potential binding when all of a binding protein is saturated with bound steroid. The capacity is governed by the amount of binding protein in the plasma. Serum albumin has a relatively low affinity for testosterone, but, given its abundance, it has a high capacity. In contrast, SHBG has a high affinity for binding steroids, but the protein is present in relatively low concentrations; however, the plasma molarity of each binding protein exceeds the plasma molarity for total testosterone concentration. The majority of testosterone bound to plasma protein is associated with SHBG. For example, Vermeulen (1973) has calculated that in the normal human male, 57% of testosterone in the plasma is bound to SHBG and 40% is bound to human serum albumin. Less than 1% is bound to corticosteroid-binding globulin, and only 2% of the total testosterone is free (see Fig. 102-4). The normal plasma free testosterone level is therefore 12.1 ± 3.7 ng/dL or 0.42 nM; this non-protein-bound "free testosterone" is bioavailable to diffuse into the sex accessory tissue and into liver cells for metabolism. In addition, a large percentage of the SHBG is saturated, whereas only a small fraction of the total capacity of corticosteroid-binding globulin and albumin is used under normal conditions. As testosterone levels increase in the plasma, the order of increasing saturation of the plasma proteins proceeds from SHBG to corticosteroid-binding globulin to albumin. Therefore, the binding of androgen is a dynamic equilibrium between various serum proteins. Because less than 5% of total testosterone is present in the free form, separate measurement of bound and free testosterone is typically not recommended, and in general only total testosterone is measured.

The total plasma levels of SHBG can be altered by hormone therapy. Administration of testosterone decreases SHBG levels in the plasma, whereas estrogen therapy stimulates SHBG levels (Forest et al, 1968; Vermeulen et al, 1969; Burton and Westphal, 1972). Estrogen also competes with testosterone for binding to SHBG, but estrogen has only one third the binding affinity of testosterone. Therefore, administration of small amounts of estrogen increases the total concentration of SHBG, and this effectively increases the binding of testosterone and thus lowers the free testosterone plasma concentration.

Because only free testosterone is bioavailable, the binding of testosterone to plasma proteins inhibits net testosterone uptake into the prostate (Lasnitzki and Franklin, 1972). It is apparent that

androgenic activity is regulated in part by the extent of binding of an androgen to the steroid-binding proteins in the plasma.

KEY POINTS: ENDOCRINE CONTROL OF PROSTATE GROWTH

- Free testosterone in the plasma is converted in the prostate by 5 α -reductase type 2 into DHT, which is 2 to 10 times more active than testosterone.
- DHT, testosterone, and estrogens are responsible for multiple metabolic actions in the prostate (growth, differentiation, and biologic functions). Free testosterone can be converted to estrogens, but estrogens cannot be converted to testosterone.

REGULATION OF PROSTATE GROWTH BY STEROIDS AND PROTEIN GROWTH FACTORS

There are multiple levels of prostate growth regulation, which include steroid hormone action, growth factors, and direct cell-cell communication and interactions with the extracellular matrix. These interactive types of growth control are accomplished by several generalized systems, as depicted in the schematic in Figure 102-6. They include the following:

- *Endocrine factors* or long-range signals arriving at the prostate by serum transport of hormone originating from the secretions of distant organs; endocrine factors include serum steroid hormones such as testosterone and estrogens and serum peptide hormones such as prolactin and gonadotropins.

Figure 102-6. Types of growth control. Endocrine signals are carried through the circulation from distant organs. Paracrine signals are produced in proximity by neighboring cells. Autocrine signals feed back on the same cells from which they are produced. Intracrine signals are a special subset of autocrine signals that never leave the cell but rather act locally within that cell. Cytokines are paracrine-like factors (typically) that are made by immune cells. Neurocrine factors are released by nerves. Cell adhesion molecules directly link neighboring cells, often through association with cognate adhesion molecules. Cells are also bound to the extracellular matrix through interactions with other cell adhesion molecules (e.g., integrins). GF, growth factor.

- *Neuroendocrine signals* originating from neural stimulation, such as 5-hydroxytryptamine (serotonin), acetylcholine, and norepinephrine.
- *Paracrine factors* or soluble tissue growth factors that stimulate or inhibit growth, which are elaborated over short ranges between neighboring cells within the prostatic tissue compartment (FGFs, epidermal growth factor).
- *Autocrine factors* that are produced and released by a cell and then fed back on the same cell's external membrane receptors to regulate its own growth or function; for example, autocrine motility factor.
- *Intracrine factors*, which function like autocrine factors but work inside the cell.
- *Extracellular matrix factors*, which are insoluble tissue matrix systems and make direct and coupled contact by being attached through integrins and adhesion molecules of the basal membrane and couple cytoskeleton organization with the extracellular matrix components, which include the glycosaminoglycans, such as heparan sulfate (Getzenberg et al, 1990).
- *Cell-cell interactions* of the epithelial or stromal cells occurring through tight membrane junctions on intramembrane proteins such as the CAMs (e.g., E-cadherin) that couple neighboring cells.

Of these seven growth control systems, the first extensively studied on the prostate was the endocrine effect of androgenic steroids, such as testosterone, in the regulation of prostate growth through changes in serum testosterone levels and conversion to DHT. However, androgens alone are not sufficient for full prostate growth. In the past two decades, extensive progress has been made in the understanding of the other systems, particularly the interactive role of growth factors and their receptors. At present, the roles of these receptors in cell signaling to the nucleus and of the structural elements in cellular control involving the tissue matrix are being developed. These mechanisms are reviewed next, starting with androgen action at the cell level beginning with the arrival of testosterone in the serum.

Androgen Action at the Cellular Level

Testosterone in the serum arrives at the prostate bound to albumin and to the steroid-binding globulins. By diffusion, free testosterone enters the prostate cell, where it is then subjected to a variety of steroid metabolic steps that appear to regulate the activity of the steroid hormone and its downstream effectors. A simplified schematic of the temporal sequence of intracellular events is depicted in Figure 102-7 and includes the following:

- Cellular uptake of testosterone.
- Testosterone conversion to DHT by metabolism of 5 α -reductase.
- DHT or testosterone binding to specific ARs in the cytoplasm.
- Dimerization and activation of the steroid receptor by a variety of post-translational steps, including, for instance, phosphorylation.
- Active nuclear transportation of the activated AR in an adenosine triphosphate (ATP)-dependent fashion.
- Chromatin remodeling through interaction with coregulatory molecules.
- Transactivation or transrepression, through interactions with other coactivators or corepressors, in a histone acetyltransferase-dependent process.
- Binding of the activated receptor-coactivator complex to androgen response elements, which are short, specific sequences of DNA recognized specifically by AR dimers.
- Gene regulation. The receptor acts as a transcription factor, and when it is bound to the DNA and matrix in proximity to androgen target genes it increases the RNA polymerase II transcription of the DNA into mRNA. The transcribed message (mRNA) is large and contains introns, exons, and a poly-A tail. The intron portion is excised from the initial RNA species, so that only the exon portion is retained in the final message. The trimming and processing of the mRNA are accomplished on the nuclear matrix as it is transported through the nucleus and out through the nuclear pore complex. The stabilized mRNA is transported into the cytoplasmic compartment to be translated at the ribosome.

Figure 102-7. Simplified schematic of the effects of testosterone in activating transcriptional targets in an epithelial cell. In the plasma, testosterone (T) is bound to serum-binding globulins (SBG), such as testosterone-binding globulin and albumin. Unbound testosterone is transported by passive diffusion into the prostate, where it is enzymatically converted to dihydrotestosterone (DHT) by 5 α -reductase (type 2) and further metabolized to diols (3 α or 3 β) and irreversibly metabolized into the more water-soluble triols (6 α or 7 α). DHT binds to a cytoplasmic receptor (androgen receptor) that is activated and translocated to the nucleus. There the androgen receptor localizes in matrix acceptor sites and subsequently activates or represses certain target genes by regulating production of their mRNA. The RNA is then transported to the cytoplasm, where it is translated into a variety of proteins (e.g., secretory proteins such as prostate-specific antigen).

into protein, which is then transported to specific cellular sites. Depending on the target gene, some proteins will undergo storage in secretory granules poised for secretion into the lumen on command during the physiologic process of ejaculation.

The epithelial cell is the primary unit in secretion, but specific genes are also activated in the stromal cells, and these events are also regulated by testosterone, estrogens, and growth factors in a similar chain of events. However, not all cells respond in the same manner to androgens or estrogens. For simplicity, these steps are discussed in relation to the epithelial cells. Androgens and estrogens, both together and separately, can affect prostate cells through interaction with receptors, and it appears that estrogens might have their primary effect on the stromal cells.

5 α -Reductase and Androgen Metabolism within the Prostate

After the free testosterone in the plasma has entered the prostate cells through diffusion, it is rapidly metabolized to other steroids by a series of prostatic enzymes (Isaacs et al, 1981, 1983; Isaacs and Coffey, 1981; Bruchovsky and Dunstan-Adams, 1985). More than 90% of testosterone is *irreversibly* converted to the main prostatic androgen DHT (Fig. 102-8) through the action of the reduced form of nicotinamide-adenine dinucleotide phosphate (NADP) and the enzyme 5 α -reductase located on the endoplasmic reticulum and on the nuclear membrane. The enzyme 5 α -reductase reduces the

unsaturated bond in testosterone between the 4 and 5 positions to form the 5 α -reduced product DHT. The K_m for testosterone is 8.3 nM, and the serum level of testosterone is only in the range of 0.5 to 3.0 nM, indicating that the enzyme cannot be saturated because the testosterone substrate would be less than the K_m value. Bruchovsky and Dunstan-Adams (1985) reported a 10-fold increase in the maximal velocity in the stromal tissue compared with the epithelium. They observed 262 pmol of DHT formed in 30 minutes per milligram of protein from testosterone measured in the stroma and less than 10% of that amount with a maximal velocity of 19 for the epithelium. The stromal K_m was 76 nM and the epithelial K_m was 13 nM. These differences between stromal and epithelial kinetics were used to deduce the existence of two different isoenzymes of 5 α -reductase (Andersson et al, 1991).

In the human, rat, and monkey there are two isozymes of 5 α -reductase (Table 102-3). The human and rat 5 α -reductase isozymes are composed of 254 to 260 amino acids with a molecular weight of 28 to 29 kD. These enzymes are N- and O-glycosylated and have a high percentage of hydrophobic amino acids that are distributed throughout the enzyme. The chromosomal localization of the human 5 α -reductase isozyme genes has been reported; the type 1 enzyme is at the extreme tip of the short arm of chromosome 5, and the human type 2 gene is on the short arm of chromosome 2. There is a 49% homology between type 1 and 2 enzymes in the human. The properties of these enzymes have been reviewed in detail by Russell and Wilson (1994), and the effects on prostate growth by McConnell (1995). The effect of finasteride

Figure 102-8. Metabolic pathways for testosterone within the prostate. Testosterone is irreversibly metabolized by 5 α -reductase to dihydrotestosterone (DHT), which is then reversibly converted into 3 α -diol and 3 β -diol. The 3 β -diol is irreversibly inactivated to the more soluble 6 α -triol and 7 α -triol. 3 α -HSD, 3 α -hydroxysteroid dehydrogenase.

TABLE 102-3 Properties and Distribution of 5 α -Reductase Types 1 and 2

	TYPE 1	TYPE 2
Chromosome	5p15	2p23
Molecular weight	29,000	28,000
Amino acids	259	254
Exons	4	4
Introns	5	5
Homology	49%	49%
pH optima	Alkaline (6-8.5)	Acidic (5.0)
K _m testosterone (μ M)	1.5	0.1-1.0
Ki finasteride (nM)	325	12
Half-life (hr)	20-30	20-30
5 α -Reductase deficiency	Normal	Mutated

on 5 α -reductase activity has been reviewed by [Rittmaster \(1994\)](#). The type 1 enzyme is in the skin and in the adult scalp and is believed to be involved in hair formation. It is present to lesser degrees in the prostate epithelium and stroma. This isoform is found in normal levels in men with congenital 5 α -reductase deficiency. The type 2 enzyme is mutated in 5 α -reductase deficiency and is the dominant isoform present in the prostate gland. The type 2 enzyme appears in the basal cells of the epithelium and in the stromal cells but is absent in the secretory epithelial cells. This has raised the possibility that DHT stimulation of epithelial cells is derived from DHT converted within the stromal or basal cells. [Silver and coworkers \(1994\)](#) have studied the cell type-specific expression of these reductases, as well as their regulation. It appears that the 5 α -reductase type 2 in the prostate does not change dramatically in individuals undergoing short-term androgen ablation.

[Berman and associates \(1995\)](#) have studied the distribution of the two 5 α -reductase isozymes in the urogenital tract of the fetal rat. At 17 to 21 days of development the expression of type 1 gene predominated in the epithelial cells; the type 2 gene was limited to the mesenchymal cells. This is true in both the testosterone-dependent and DHT-dependent anlagen of the urogenital tract. These investigators observed that androgens could stimulate the expression of the type 2 gene in the urogenital tract but not of the type 1 gene. They suggested that the type 2 5 α -reductase gene exhibits positive feedback control in that the product of the enzyme, DHT, can stimulate expression of the gene; however, no evidence for such regulation of either 5 α -reductase gene was detected in the fetus.

In summary, 5 α -reductase is of great importance because the product DHT is important in the differentiation of the prostate during fetal development and because mutations in 5 α -reductase give rise to a rare form of pseudohermaphroditism. In prostate physiology, expression of the 5 α -reductase gene is regulated by androgens in both the prostate and liver. It is also believed that 5 α -reductase is involved in male pattern

baldness, acne, and hirsutism as well as in BPH. The 5 α -reductase inhibitors finasteride (type 2 inhibitor) and dutasteride (type 1 and 2 inhibitor) are clinically useful drugs in the treatment of BPH and male pattern baldness when they are given to appropriate patients.

After DHT is formed from testosterone in the prostate, it is then subjected to a series of reversible metabolic reactions to form 3 α -diol (5 α -androstane-3 α ,17 β -diol) and 3 β -diol (5 α -androstane-3 β ,17 β -diol) (see [Fig. 102-8](#)). The enzymes that perform this transformation of DHT are 3 α - or 3 β -hydroxysteroid oxidoreductases. These enzymes use NADP as a cofactor, but in contrast to 5 α -reductase they can also use nicotinamide-adenine dinucleotide (NAD). The equilibrium for the metabolism of DHT favors the formation of DHT, that is, the 3-hydroxy group of 3 α -diol and 3 β -diol is oxidized to the 3-ketone that is present in DHT. It is known that 3 α -diol administered to animals is a strong androgen through its rapid conversion to the effective DHT. On the other hand, 3 β -diol is not effective as an androgen because it is rapidly and irreversibly converted to the triol form by hydroxylation in the 6 α or 7 α position (see [Fig. 102-8](#)). The triols are dead-end products of testosterone metabolism but are water soluble and inactive as androgens because they cannot re-form DHT. Steroids also can form glucuronide or sulfate conjugates and be secreted in a more soluble form. In summary, testosterone is irreversibly metabolized to DHT that is in equilibrium with other reduced steroids primarily through oxidation and reduction at the 3 position. The steroids are inactivated by being irreversibly hydroxylated to the inactive triols.

Androgen Regulation of Stromal-Epithelial Interactions

It is now apparent that there is a dynamic and reciprocal interaction between the functions of epithelial cells and those of stromal cells ([Steiner, 1993](#); [Cunha, 1994](#); [Sikes et al, 1995](#); [Cunha et al, 2003, 2004](#)). These crosstalk interactions are mediated through the spatial organization of extracellular matrix elements that form the basement membrane linkage. This linkage presents, filters, and organizes the two-way paracrine signals and the flow of information between those two cellular compartments. For example, fluids, gases, nutrients, hormones, and many growth factors arriving in the prostate through the circulation must first pass through the stromal ground substance, the extracellular matrix, and the basement membrane before reaching the base of the secretory epithelial cells. Early in development, the functions of the epithelial and mesenchymal (stromal) elements vary as to their cell types, compositions, properties, and interactions. It is the integrated system biology of these two tissue elements as well as their dynamics during aging that play a vital role in the prostate's functions as a unit and gland. Indeed, it is the breakdown of these tissue interactions that is one of the hallmarks of the abnormal growth of the prostate that starts very early in life and is initiated at some time just after maximum virilization, at approximately 25 years of age. The prostate is extremely susceptible to permanent early alterations in form and structure as a consequence of genetic, environmental, dietary, or metabolic factors with aging ([Risbridger et al, 2005](#)). In fact, it is essential to establish the link between hormonal (androgens and estrogens) changes that occur during the fetal or neonatal period that imprint and hence may result in onset of late-life disease. With aging, during a period of 50 to 60 years, this organ slowly progresses through the transition from normal zonal histologic anatomy and function to the early signs of BPH, to prostatic inflammatory atrophy, to prostatic interepithelial neoplasia, and finally to various types of prostatic adenocarcinoma. This concept has been thoroughly documented in several rodent models ([Rajfer and Coffey, 1978, 1979](#); [Naslund and Coffey, 1986, 1987](#); [Prins and Birch, 1995](#); [Singh et al, 1999](#); [Prins et al, 2001](#); [Risbridger et al, 2005](#)).

Cell Adhesion Molecules

Cell-cell and extracellular matrix interactions are becoming major targets for understanding how the phenotype of a cell is regulated.

Transmembrane receptors on the cell surface extend out through the plasma membrane and form a bridge directly connecting the cytoskeleton with proteins and receptors located within the extracellular matrix or on neighboring cells. The CAMs are divided into four major types: (1) integrins, which link the cell to the basement membrane and extracellular matrix components through heterodimer interactions; (2) cadherins, which link the cell to neighboring cells through homotypic polymers; (3) selectins, which link the cell to carbohydrate moieties primarily on the vascular system; and (4) immunoglobulin (Ig) superfamily adhesion molecules. The most extensively studied of these CAMs in the prostate in order of interest have been E-cadherins, which bind PrECs to one another, and CD71, which binds to transferrin, as well as several of the integrin molecules. These bindings have been surveyed in prostate tumor cell lines in vitro (Rokhlin and Cohen, 1995), but more extensive work needs to be carried out in vivo in the normal developing prostate and in prostate cancer.

The integrins are made up of two covalently linked heterodimers termed α and β subunits. These integrins serve externally to contact the extracellular matrix receptors of fibronectin, fibrinogens, collagen, and laminin as well as glycosaminoglycans in the proteoglycans of the extracellular matrix. The integrin receptor domains inside the cell compartment serve as focal points for determining the structure and organization of the cytoskeleton. Approximately eight subunits of α and β can interact in different heterodimers that are tissue specific and can be of several types even on one cell. Different combinations may have varying degrees of binding activity for extracellular matrix components. For example, $\alpha_3\beta_1$ binds to laminin, collagen, and fibronectin and does so by recognizing a triplet of amino acids in those proteins made up of arginine, glycine, and aspartic acid (RGD).

Other types of transmembrane receptors also extend out of the cell to make direct cell-cell contact with the neighboring cell by recognizing similar receptors and forming homodimer bonds. Certain homophilic dimers that require calcium for interactions to form cell-cell bonds with neighboring cells are termed *cadherins*. Four of the cadherin types have been cloned. They contain 723 to 748 amino acids that are composed of a single peptide, an extracellular region with three repeated domains, a hydrophobic transmembrane region, and a long cytoplasmic tail. There is approximately 50% homology across species and between integrins. The cadherins are classified into three subtypes: E-cadherins, found in adult epithelial cells (also earlier termed *uvomorulin*, cell CAM 120/80, ARC-1, or L-CAM); N-cadherins, found in neural tissues of muscle (also termed A-CAM); and P-cadherins, found primarily in placenta and epithelium (Albelva, 1994). In the prostate cell, for example, E-cadherins extending out of the surface membrane make contact with the neighboring cell and form a homodimer, and the E-cadherin extending inside the cell by passing through the membrane would form as an organizing center that binds a complex of three cytoplasmic proteins termed *catenins* α , β , and γ . This complex is localized to the zonula adherens of the cell and participates in junction formation and stabilization of the cytoskeleton. These interlocking matrix systems interact to form a structural network extending externally from cell-cell contact and the extracellular matrix interactions and then internally to cytoskeleton organization and centrally, terminating by direct contact with the nuclear matrix that forms tissue-specific DNA organization.

The interactions of the nonhistone tissue matrix regulate many aspects of DNA functions involved in growth and differentiation (Getzenberg et al, 1990; Boccardo et al, 2003). The nonhistone proteins such as high-mobility group (HMG) proteins include HMGI/Y (HMGA) that participate in numerous cellular processes, such as regulation of inducible gene transcription, integration of retroviruses into chromosomes, and induction of malignant transformation (Reeves and Beckerbauer, 2003). Through protein-DNA and protein-protein interactions, the members of the HMGA family can influence growth, cell proliferation, differentiation, and cell death; they influence chromosome dynamics by acting as architectural transcription factors affecting several genes that have an impact on tissue structure and organization. This class of genes is often

upregulated in cancer (Reeves and Beckerbauer, 2003). These types of tissue matrix interactions are essential to the understanding of stromal-epithelial interactions because they form direct structural linkages and communications between the stroma and the epithelial nuclear DNA. In summary, under the influence of hormones (estrogens and androgens) and diet, it is the regulation of chromatin structure and organization through the histone and nonhistone pathways that replaces and maintains the tissue organization as well as interactions in health and disease.

The discussion, to this point, has concerned primarily insoluble elements in inducing stromal-epithelial interactions, but soluble hormones such as steroids, vitamins, and growth factors are also important (Sikes et al, 1995). The prostate stromal cells contain steroid receptors and respond to both androgens and estrogens (see earlier discussion). Androgens and estrogens can alter the formation of collagen (Coffey and Walsh, 1990) and other extracellular matrix components, such as glycosaminoglycans, in the prostate (DeKlerk et al, 1984; DeKlerk and Human, 1985; Kofoed et al, 1990; Horsfall et al, 1994).

In summary, different components of matrix interactions can have either an inhibitory role in negative regulation of normal prostate growth or a positive role in establishing tumor growth. There have been many hypotheses concerning the mechanism of these epithelial-stromal interactions, but they have yet to be fully resolved.

KEY POINTS: CELL ADHESION MOLECULES

- Transmembrane receptors on the cell surface extend out through the plasma membrane and form a bridge directly connecting the cytoskeleton with proteins and receptors located within the extracellular matrix or on neighboring cells.
- The CAMs are divided into four major types: *integrins*, which link the cell to the basement membrane and extracellular matrix components through heterodimer interactions; *cadherins*, which link the cell to neighboring cells through homotypic polymers; *selectins*, which link the cell to carbohydrate moieties primarily on the vascular system; and Ig superfamily adhesion molecules.

REGULATION OF PROSTATE GROWTH AT THE MOLECULAR LEVEL: STEROID RECEPTORS

In almost all cells in the body, steroids can enter the nucleus, but only a few cells can retain this steroid within the nucleus for any length of time. The cells that retain the steroid have receptors that are steroid specific, which can regulate specific steroid-sensitive genes within the nucleus to alter the expression of certain proteins. The AR's affinity for the nuclear acceptor site to which it binds in the nucleus is probably a compilation of binding to specific sequences on DNA (androgen response elements) as well as tissue-specific binding to coregulatory factors. The uptake and binding of the AR in the nucleus are regulated by the presence of the androgen ligand bound to the receptor, resulting in receptor activation. When androgens are not present, the receptor decreases its affinity for nuclear binding and can easily be removed; indeed, under castrate conditions, receptors may leak back out into the cytoplasm (Husmann et al, 1990). Immunohistochemical techniques indicate that in the presence of androgen the AR localizes primarily to the nucleus.

The prostate and seminal vesicles contain steroid-specific and high-affinity (10^{-9} to 10^{-10} M K_d) saturable (100 to 1000 fmol of receptor per milligram of DNA equivalents of tissue) ARs that were first described by Liao and Fang in 1969. There are 5000 to 20,000 molecules of these receptors per cell, far more than can bind to the androgen response element sites, which are probably fewer than 400. Classic AR function has been characterized as a genomic

process, wherein certain transgenes are regulated by the activated AR. More recently, however, attention has been focusing on the nongenomic mechanisms of androgen action (Benten et al, 1997; Jones et al, 2004). Nongenomic androgen action is characterized by extremely rapid changes in cellular physiology, typically measured in seconds or minutes, as opposed to the longer times required for target gene regulation to be translated into protein changes. Whether nongenomic androgen action occurs through the same ARs involved in genomic regulation still remains to be determined. The properties and hormonal regulation of ARs as well as their uses have been reviewed in detail (Germann, 2002; Black and Paschal, 2004; McEwan, 2004).

Androgen Receptor

The cloning of the human AR and its expression was a hallmark in the study of the mechanism of androgen action (Chang et al, 1988b; Lubahn et al, 1988). This led to the study of the sequence of the gene and its protein product—and how this is altered in inherited androgen insensitivity syndromes—as well as receptor function (Chang et al, 1995).

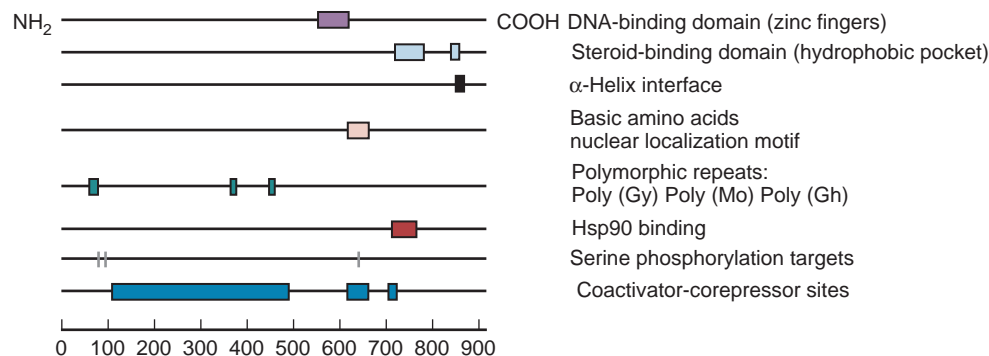

The AR gene is on the long arm of the X chromosome at position Xq11.2-q12. Because there is only one X chromosome in a male, it is a single-copy gene. The coding sequence on this gene is divided into eight exons that are transcribed and processed into mRNA and then subsequently translated into protein. The total genomic DNA spans a minimum of 80 kilobases (Marcelli et al, 1990) but forms a final message of only 10.6 kilobases, that is, only 17% of the total gene, with an open reading frame of 2757 base pairs. This is similar to the organization of many other steroid receptors that also contain information from eight exons, such as the progesterone and ERs. The AR is a member of the nuclear receptor superfamily, which is a group of ligand-inducible transcription factors. The nuclear receptor superfamily has more than 200 members at present (Escriva et al, 2004). All of these receptors share certain structural features that allow them to regulate gene expression, although the ligands for many of these receptors have yet to be identified (so-called orphan receptors). Such receptors include the glucocorticoid receptor, the retinoic acid receptors (RXR and RAR), the vitamin D receptor, the estrogen and progesterone receptors, the peroxisome proliferator-activated receptor (PPAR- γ), and many orphan receptors. Like other steroid receptors, the AR is divided into three distinct, modular domains: the amino-terminal domain, the DNA-binding domain, and the carboxyl-terminal ligand-binding domain. Despite the similarity in structural organization of all of the nuclear receptors, activation of different receptors results in markedly different cellular responses. Mutational analyses of the

human AR have allowed a detailed mapping of a variety of different functions, which are diagrammed schematically in Figure 102-9.

Upstream (5' direction) of the transcriptional initiation site is the regulatory element of the gene that controls its expression. It is unusual in that it contains the GC box rather than the classic TATA and CCAAT, which are commonly found in promoters of polymerase II-dependent genes. Closer to the initiation site located only 70 base pairs upstream is a 50-base pair purine-rich region that is a *cis*-acting element for AR transcription. There are other *cis*-acting elements, including an AP-1 (which is bound by a heterodimer of c-Fos and c-Jun) and a RARE (retinoic acid response element) as well as a cyclic adenosine monophosphate (cAMP) response element (AR/CRE1). This suggests that the regulation of expression of the AR gene may involve cAMP, activation of c-Fos/c-Jun, or retinoids (Kuiper et al, 1989; Faber et al, 1993; Mizokami et al, 1994; Young et al, 1994). Activation of the AR appears to be a function of multiple steps including initial complex formation with certain chaperonins, binding of ligand, post-translational modifications, dimerization, nuclear localization, and binding of the receptor to certain transcriptional coactivator complexes that remodel chromatin, target the initiation site, and stabilize the RNA polymerase II machinery for repeated rounds of transcription. Each of these features is discussed in the context of known structural features of the receptor as diagrammed in Figure 102-10.

Chaperonin Binding

Immediately after nascent production of the protein in the ribosome, the receptor forms complexes with several other proteins, referred to as *chaperonins*. These chaperonins form an aggregate complex, which is known as the 8S complex, in reference to the size of the complex on sucrose gradient sedimentation analysis. This chaperonin complex includes at least eight known components (Hsp90, Hsp70, Hip, p60, p23, FKBP51, FKBP52, and Cyp40), which serve to sequester the receptor into an inactive pool (see Fig. 102-10). By analogy to the progesterone receptor, which has had the most detailed scrutiny in regard to the molecular biology of the chaperonin complex (Nair et al, 1996; Pratt and Toft, 1997; Smith, 2000), the AR can dissociate into a monomeric form (4S on sucrose gradient centrifugation) that is in equilibrium with the 8S form, with the preponderant species existing in the chaperonin complex. This larger complex may be particularly favored by virtue of mass action alone, because the heat shock proteins tend to be among the most abundant proteins in the cell. Although the AR is uncomplexed, it is susceptible to various different post-translational processing steps, including phosphorylation or glycosylation. Such interactions may then inhibit reassociation with the chaperonins,

Shown are the coordinates of all known functional elements

Figure 102-9. Structure of the human androgen receptor protein. The androgen receptor is divided into several functional domains including the DNA-binding domain (consisting of two zinc fingers), a steroid-binding domain (consisting of a hydrophobic pocket), a nuclear localization motif, and several coactivator-corepressor binding sites. There are three polymorphic repeats of glycine, proline, and glutamine, with varying sizes among different populations. The relative positions of the functional elements are shown to scale.

Figure 102-10. Mechanism of androgen receptor (AR) activation by ligand. Androgen enters the cell membrane by passive diffusion and binds the androgen receptor in the cytoplasm. The AR exists in equilibrium with the chaperonin complex, consisting of at least eight different components, including Hsp90, Hsp70, Hip, p60, p23, FKBP51, FKBP52, and Cyp40. Once activated by binding ligand, post-translational modifications occur, such as phosphorylation. Contemporaneously, dimerization occurs, and the activated modified androgen receptor is translocated to the nucleus by active transport.

leading to ligand-dependent activation, ligand-independent activation, or receptor inactivation with proteasome-mediated degradation. Evidence for such a mechanism includes a PEST sequence similar to one in the vitamin D receptor that is present in the hinge region of all known mammalian ARs, suggesting that it may function in proteasome-mediated AR turnover. Moreover, proteasome inhibition leads to a significant increase in AR isoforms (Sheflin et al, 2000).

DNA-Binding Domain

Near the end of exon 1 and extending into exon 3 is the coding sequence for the DNA-binding domain. The DNA-binding domain of the AR consists of 72 amino acids rich in cysteine and encoding two zinc finger motifs, which allows specific recognition of certain DNA sequences referred to as *androgen response elements*. Such elements typically consist of a palindromic repeat separated by a three-nucleotide spacer—for example, GG(A/T)ACAnnnTGTCT (Roche et al, 1992). X-ray crystallography of certain steroid receptors (glucocorticoid receptor and progesterone receptor) has shown that the first zinc finger directs sequence specificity of binding by directly contacting the DNA bases in the major groove; the second zinc finger functions to stabilize the protein-DNA complex by contacting the sugar-phosphate backbone. Although the protein-DNA interaction appears to be largely limited to the zinc finger motifs, sequences in the amino terminus appear to be important in stabilizing these structures because mutations in this region result in a mildly diminished DNA-binding affinity. This DNA-binding domain of the zinc

fingers in the steroid receptor molecule is highly conserved. In this region of exon 2 to 3, there is a 79% homology with the progesterone receptor, a 76% homology with the glucocorticoid receptor, and a 56% homology with the ER (Chang et al, 1988a, 1988b). The closest homology of the AR is with the progesterone receptor (Lubahn et al, 1988; Marcelli et al, 1990). Mutations of amino acids in this area of the AR can make the receptor unable to activate androgen-sensitive genes (Govindan, 1990), which is the basis of one of the inherited androgen-insensitivity syndromes—testicular feminization.

The DNA-binding domain binds to its cognate DNA-regulatory site, referred to as a *hormone response element*. Hormone response elements can be divided into different groups on the basis of common structural features for which whole groups of receptors are capable of binding. Class I hormone response elements include the glucocorticoid receptor, the progesterone receptor, and the mineralocorticoid receptor and are characterized by a half-site consensus sequence of TGTCT. Class II hormone response elements include the ER, whose prototype half-site sequence is TGACC. The hormone response elements to which ARs have been shown to bind belong to the class I subgroup (Tan et al, 1990). A consensus sequence for the androgen response element has been determined by an RNA-binding site selection assay with an AR fusion protein to be GG(A/T)ACAnnnTGTCT (Roche et al, 1992). Such binding sites are characterized by an inverted palindromic repeat with a dyad axis of symmetry, indicating that the receptors are binding in a head-to-head fashion. However, the androgen response element of the rat probasin promoter has been found to be a direct repeat

(Schoenmakers et al, 2000). Surprisingly, x-ray crystallography data reveal that AR dimers bind to direct repeat target sequences in a head-to-head fashion, maintaining the normal orientation of an inverted repeat target sequence (Shaffer et al, 2004). To date, only the AR has been found to bind to a direct repeat target sequence with an orientation normally expected for an inverted repeat. This difference may represent one way ARs maintain specificity of target gene regulation.

Ligand-Binding Domain

Ligand-dependent activation is characterized by ligand-receptor dimerization, post-translational modifications (e.g., phosphorylation), nuclear translocation, and subsequent target gene activation (or repression). It is believed that binding of either DHT or testosterone to the ligand-binding domain can facilitate these processes, although the binding affinity for DHT is significantly higher than for testosterone. Binding of the androgen to the carboxyl-terminal ligand-binding domain is required for activation; however, deletion of the ligand-binding domain can lead to a constitutively active AR. In prostate cancer, various splice isoforms have been identified that lead to constitutively active function (Hu et al, 2011). Thus, at least part of the interaction with the chaperonin complex involves the carboxyl portion of the receptor (Marcelli et al, 1990). However, small point mutations in the ligand-binding region can lead to significant changes in the characteristics of AR action. For instance, a single point mutation in the ligand-binding domain of the AR (codon 877, Thr→Ala) identified in the LNCaP cell line of prostate cancer renders it weakly inducible by inappropriate steroids such as progesterone while it retains the ability to be stimulated by androgens. Marcelli and coworkers (1990) reported that mutations in the AR at amino acid 587 or 794 are inactive in the assay for androgen binding and for transcriptional activation. However, the removal of amino acids from 708 to the carboxyl end at 917 (i.e., the entire ligand-binding domain) leads to the synthesis of a receptor protein that does not bind androgens but is still constitutively active in activating transgenes. As new drugs have become available for prostate cancer androgen axis suppression, resistance to these new agents (e.g., abiraterone and enzalutamide) may involve some of the AR splice isoforms, or potentially even upregulation of other steroid receptors (Sharifi, 2014).

Dimerization

The identification of the palindromic structure of certain hormone response elements for all steroid receptors led to the proposal that these transcription factors bind to the DNA as a dimer. Subsequent analysis of the receptor-DNA interactions has confirmed this hypothesis, and dimerization is now thought to represent an important step in the regulation of steroid receptor action. A hydrophobic heptad repeat within the ligand-binding domain at codons 859 to 880 is conserved among all steroid receptors and is thought to be necessary for high-affinity dimerization. Removal of these sequences leads to low-affinity dimerization, presumably through the action of the DNA-binding zinc fingers on the palindromic androgen response elements. Abolishment of the DNA-binding domain does not inhibit the strong affinity dimerization present in the ligand-binding domain. The strong dimerization signal appears to be related to a hydrophobic α -helix interface formed by the conserved heptad (Centenera et al, 2008).

Post-Translational Modifications

Once the AR has been bound to steroid ligand and dissociated from the chaperonin complex, it is susceptible to a variety of post-translational modifications, any one of which may significantly affect the function and turnover of the receptor. For instance, the AR can be acetylated (Fu et al, 2004) or phosphorylated (Goueli et al, 1984). In the rat ventral prostate it has been reported that this occurs through a nuclear cAMP-dependent protein kinase (Kempainen et al, 1992). Receptor phosphorylation may be an

important mechanism in the nuclear translocation of steroid receptors as well as in DNA binding and transcriptional regulation. The stimulation for phosphorylation appears to be optimal with the binding of an androgen agonist, because antagonists such as flutamide appear to favor the dephosphorylated state, suggesting that the phosphorylation status may be associated with the ultimate activity of the receptor (Wang et al, 1999). Both serine and tyrosine residues have been found to be phosphorylated in other steroid receptors (Landers and Spelsberg, 1992; Sadar et al, 1999). In addition to phosphorylation by protein kinase A, ARs also appear to stimulate mitogen-activated protein kinases, which may provide a different level of regulation of gene activity because such kinases often modulate other transcription factors, such as Elk-1 (Peterziel et al, 1999). The prostate is a rich source of acid phosphatases, and some have suggested that these enzymes may be active in regulating the phosphotyrosyl residues of the AR, thus playing a role in dephosphorylation and inactivation of ARs (Goldsteyn et al, 1989), although this relationship is certainly not causal.

Nuclear Localization

After activation by the binding of steroid ligand the AR is transported to the nucleus across the nuclear pore complex by a process involving at least two nuclear localization signals, one for import and one for nuclear export. Evidence for nuclear localization signal-dependent nuclear translocation is well established and can be found in a variety of nuclear proteins, including the SV40 large T antigen. In most cases it consists of a stretch of basic amino acids. The prototype nuclear localization signal from the SV40 large T antigen is PKKKRKV, although various other basic sequences have also been implicated in nuclear localization signaling. The nuclear localization of the AR appears to involve multiple steps, including the binding of the basic amino acid nuclear localization signal to importins α and β , docking of an importin-cargo complex to the nuclear pore, translocation to the nucleus, and Ran-GTP-mediated release of the cargo (Rao et al, 2002). Two regions of steroid receptors have gained most attention as regulators of receptor trafficking. The first region is the second DNA-binding zinc finger region, together with the flanking hinge region (NL1) consisting of a bipartite signal including flanking leucines and the core signal ⁶²⁸RKLLK-KLGN (Kempainen et al, 1992; Ylikomi et al, 1992; Poukka et al, 2000). However, this one putative nuclear signal peptide is not sufficient by itself for high-efficiency translocation; and by analogy to other steroid receptors, additional nuclear localization signals may exist in the steroid-binding domain (Kempainen et al, 1992). NL1 acts constitutively and participates in rapid nuclear import that is facilitated by importin- α binding (Savory et al, 1999). A number of coregulators of steroid receptor-mediated transactivation interact with regions that encompass NL1 (Jackson et al, 1997; Moilanen et al, 1998; Powers et al, 1998; McKenna et al, 1999). Some of these proteins, such as SNURF and Ubc9, lose their ability to interact with AR when the region overlapping with the bipartite NL1 is destroyed (Moilanen et al, 1998; Poukka et al, 2000). A second signal, NES^{AR}, is located in the ligand-binding domain (Saporita et al, 2003) and is a nuclear export signal that facilitates export of AR when it is not complexed to ligand. Between the NL1 and NES^{AR}, the AR is actively shuttled between the cytoplasm and nucleus, presumably to tightly regulate its intrinsic ability to activate or repress gene expression.

Transcriptional Activation Domains

Once the AR has achieved active localization into the nucleus it must find and bind to its target sequences in the genomic DNA. The precise mechanism by which receptor localization occurs to target genes is still unknown; however, there is emerging evidence indicating it is a highly orchestrated process (O'Malley, 2008). For instance, it is now known that so-called pioneer factors such as FOXA1 are targeted to specific chromosomal sites by epigenetic signaling, and then the ARs bind to these sites to subsequently regulate the target genes (Lupien et al, 2008). Once the AR has properly localized within the target chromatin sites, it must coordinate

Figure 102-11. Mechanism of action of the nuclear-activated androgen receptor (AR). Once the androgen receptor has been translocated to the nucleus it undergoes several steps (many of which may occur contemporaneously): (1) chromatin remodeling in an adenosine triphosphate (ATP)-dependent fashion via the SWI-SNF complex; and (2) agonist (i.e., dihydrotestosterone [DHT])-mediated histone acetylation in a process involving multiple transmission factors including p300, CBP, and SRC1. In the case of a certain antagonist, histone deacetylation may be favored, and the activated nuclear receptors complex with repressors of gene expression such as N-CoR and SMRT. (3) The activated androgen receptor complexes then associate with other γ -trans-acting factors via the TRAP/DRIP (thyroid receptor-associated protein/D receptor-interacting protein) complex at sites typically upstream of the target gene known as *androgen response elements*. This complex then leads to androgen-regulated activation of gene expression.

binding to a number of associated factors referred to as *coactivators* and *corepressors* that subsequently regulate gene expression (Fig. 102-11). A list of recently identified coactivators is provided in Box 102-1. Most of these factors interact promiscuously with many steroid receptors, although more AR-specific factors are routinely being discovered. Because the number of potential coregulators clearly exceeds the capacity for direct interaction by a single receptor, the most likely mechanism is that transcriptional activation by AR involves multiple factors that act in both a sequential and a combinatorial manner to reorganize chromatin templates (Pollard and Peterson, 1998). The precise timing and sequence of binding of these factors remain to be elucidated; however, in general, one can break down the processes empirically into chromatin or nucleosomal remodeling (an energy-dependent process), histone acetyltransferase activity, and subsequent recruitment of TATA-binding protein (TBP)-associated factors, all of which promote an increased rate of gene transcription by RNA polymerase II. Under certain conditions, such as binding of an AR antagonist (e.g., flutamide), the histone acetyltransferase activity is actually inhibited and transrepression may occur. Such inhibition of gene expression appears to involve the nuclear corepressor proteins N-CoR and SMRT (Glass and Rosenfeld, 2000). Other proteins may play a similar role, such

as the *HBO1* gene (Sharma et al, 2000). Amino-terminal deletions in region 46-408 result in dominant negative suppression of hormone-inducible transgene activation, indicating that the coactivator functions require an interaction within that site and that in the absence of this region the receptor forms dysfunctional complexes in the chromatin (Palvimo et al, 1993).

The transcription domain of the AR is coded in exon 1, which is the largest of the exons, containing 1607 base pairs. Analysis of this region reveals three homopolymeric repeated regions, including a repeat of approximately 20 glutamines, followed by a space containing 8 repetitive prolines and 23 repetitive glycine units (see Fig. 102-11). The glutamine repeats form a β sheet that helps form a polar zipper, which favors certain protein-protein interactions. Fusion of this type of polymeric glutamine repeat with the DNA-binding domain of GAL4 in yeast results in a GAL4-directed increase in transcriptional activity, demonstrating the importance of this region in promoting transgene activation (Gerber et al, 1994).

Studies demonstrate that these polyglutamine repeats appear to interact directly with the carboxyl terminus of the transcription factor p160 (Irvine et al, 2000). In the normal population this repeat varies over a length of 11 to 31 residues, resulting in a true allelic polymorphism. This means that different people have alleles

of variant polyglutamine repeat units. This variation is racially defined, and it has been suggested that this may be related to the differences in the incidence rates of prostate cancer in different ethnic groups. The most common CAG repeat length in whites is a modal value of 21; in African-Americans, it is shorter at 18; and in Asians, it is longer at a mean of 23. The longer the glutamine repeats, the lower the activity of the AR in activating target genes. Patients with X-linked spinal and bulbar muscular atrophy, termed *Kennedy disease*, possess a larger glutamine repeat in the range of 40 to 60. The ARs in Kennedy disease exhibit markedly less transactivation activity (Laspada et al, 1991). Moreover, men with male factor infertility are found to have longer than average polymorphisms of the AR than normal controls (Tut et al, 1997). Genetic studies of inherited diseases of androgen insensitivity and overvirilization as well as changes in the AR mutation associated with prostate cancer and its biologic properties will be of great help in unraveling the role of the human AR in relation to its structure.

KEY POINTS: ANDROGEN RECEPTOR

- The AR, an intracellular steroid-binding protein, is activated by androgens, resulting in both genomic and nongenomic actions, which in turn regulate cellular action.
- This regulation is central to prostate development, growth, and homeostasis and occurs in both the stromal and epithelial compartments.

Androgen Receptor–Dependent Chromatin Remodeling

Part of the tissue and gene specificity in the recognition of receptors and DNA may depend on the organization of the DNA within the nucleus (Getzenberg et al, 1990). The steroid-receptor complex can interact only with genes that are in regions that are “open” or in the transcriptionally active form. Studies show that these open regions of chromatin (euchromatin) can extend up to 100,000 base

pairs in length, or more than 10-fold the size of a typical gene, which usually ranges from 1000 to 10,000 base pairs. It is unknown how such a large range of DNA is altered in conformation, but it may be through binding to structures like the nuclear matrix, which can order large loop domains in the region of 60,000 to 120,000 base pairs. Nuclear receptors are thought to interact with chromatin remodeling complexes in an ATP-dependent fashion, in a process directed in part by “pioneer factors” including FOXA1 (Lupien et al, 2008), and this may be among the earliest steps in the ultimate regulation of certain target genes (Glass and Rosenfeld, 2000).

During cell division, chromosomal organization is spatially regulated at each of the critical phases of mitosis (Williams and Fisher, 2003). Epigenetic regulation of chromosome structure and function is highly ordered during cell division, differentiation, and development (Lam et al, 2005; Margueron et al, 2005). In fact, chromosomal proteins are required to maintain such ordered structure for euchromatin, heterochromatin, and centromeric chromatin to sustain normal cell and tissue functions. To achieve such coordinate regulation, the protective packaging of DNA is engineered through an elegant system of tightly wound DNA around an eight-component histone core called a *nucleosome*. This core consists of dimers of H2A, H2B, H3, and H4, whose ability to compact DNA is directly regulated by post-translational modifications. The selective regulation of such post-translational histone modification constitutes a major regulatory mechanism for gene expression and is referred to as the *histone code* (see Fig. 102-11). Histone modifications include acetylation, phosphorylation, ubiquitinylation, and methylation (Downs and Jackson, 2003; He et al, 2003; Cosgrove et al, 2004; Cosgrove and Wolberger, 2005; Lam et al, 2005).

ARs are known to interact with structural components of the chromatin organizing complexes. Such complexes include the multisubunit human SWI-SNF complex, which has been shown to remodel mononucleosome and polynucleosome templates in an ATP-dependent manner (Peterson and Tamkun, 1995). The isolated hSWI-SNF ATPase subunits BRG1 and hBRM also have these activities (Phelan et al, 2000).

The transcriptional activation of nuclear receptors (neuroendocrine cells) requires multiple factors including SWI-SNF complex, CPB/p300, and steroid receptor coactivator (SRC) family members, which are large and contain numerous subunits, many of which make contact with a variety of nucleosome components and the nuclear matrix (Huang et al, 2003). Such components include BAF53a, BAF57, BAF60, BAF110, BAF155, BAF170, BAF250, BRG1, BRM, and SNF5. Because condensed chromatin renders genes inaccessible for transcription, the combination of a steroid receptor and SWI-SNF complex formation appears to be critical for appropriate nucleosomal remodeling to allow appropriate target genes to be accessible for gene regulation (Sudarsanam and Winston, 2000; Huang et al, 2003). Once the receptor SWI-SNF complex, CPB/p300, and other mediators have successfully “opened” the structure of the chromatin to allow transcriptional regulation, the AR must interact with a distinctly different set of cofactors. Post-translational histone modification clearly appears to be requisite for chromosome remodeling and optimal gene expression (Ewen, 2000; He et al, 2003). In most models tested the rates of gene transcription actually correlate with the degree of modification of histones through acetylation, phosphorylation, ubiquitinylation, and methylation. In other words, hyperacetylated histone regions correspond to the highest gene-transcriptional regions, whereas the hypoacetylated histone regions correspond to the lowest gene-transcriptional regions (Pazin and Kadonaga, 1997). A number of histone acetyltransferase complexes have been found to be associated with nuclear receptors, including the AR. These complexes include p/CAF, a homolog to the yeast GCN5, which participates in the yeast SAGA complex. This complex includes factors that possess activity but also TBP and a number of TBP-associated factors. The p/CAF protein has been found to be associated with the retinoic acid receptor and may be involved with multiple nuclear receptors. It is also known to bind to other histone acetyltransferase (HAT) proteins, including CBP/p300, which is known to acetylate not only histones but other transcription factors as well. The CBP/p300

complex is an essential coactivator for many genes and may actually serve as a molecular scaffold in stimulating gene transcription (McKenna et al, 1999; Huang et al, 2003; Marshall et al, 2003). Such complexes include the SRC1 coactivator, among others. More recently, the modifiers of the histone code have expanded considerably to include sophisticated enzyme-mediated alterations in the histones H2A, H2B, H3, and H4 by phosphorylation, ubiquitinylation, and methylation, which open the chromatin, allowing the recruitment of important transcription factors that allow normal cell functions (Lam et al, 2005; Margueron et al, 2005). The list of coactivators associated with nuclear receptors and the AR in particular is extensive and almost certainly incomplete. A short list of factors found to be associated with the receptor at this level of gene regulation is given in Box 102-1. Among the most important factors is SRC1, which has mild HAT activity and seems to be required for optimal stimulation of steroid-dependent transcription. Additional factors include steroid receptor RNA activator (SRA), a structural RNA necessary for the coactivator complex to function optimally (McKenna et al, 1999), and p160 coactivator, which appears to be required for hormone-dependent activation and to directly interact with the polyglutamine repeats found in the amino-terminal transactivation domain (Irvine et al, 2000).

Most genes have a regulatory region immediately upstream of the transcriptional start site. The regulatory region is divided into a core *promoter element* that is present in all genes as well as other upstream elements that serve to regulate the overall gene expression pattern. This promoter element specifies the site to which RNA polymerase II will attach to the DNA and will determine the actual point for the initiation of transcription. The RNA polymerase will copy or transcribe the DNA code into mRNA, a process termed *transcription*. This promoter area starts at -16 nucleotides to +32 upstream from the gene initiation site. This region of -32 to +16 was originally referred to as the *Goldberg-Hogness box* or *TATA box* and has a consensus sequence of TATAAAAG. The RNA polymerase II enzyme binds to this TATA box as one of the initial steps in transcription. Farther upstream from the TATA box is a second gene control element termed generically the *hormone response element*, which has been identified in many genes regulated by steroid hormones and is one of multiple sites where the receptor binds to the DNA. As stated earlier, in androgen-regulated genes, this area is termed the *androgen response element*; in estrogen, the *estrogen response element*; and in glucocorticoid, the *glucocorticoid response element*. This hormone response element area may contain several discrete sequences, but its overall role is to modulate the frequency of transcription initiation vis-à-vis interactions with transcriptional factors. In independent analysis, thyroid hormone receptors were found to be associated with affinity purified proteins, which were found to markedly enhance ligand-dependent cell-free transcription. This complex was referred to as *TRAP*, for thyroid receptor-associated proteins (Fondell et al, 1996). In a similar set of experiments, the same type of complex was isolated for the vitamin D receptor and was called *DRIP* for D receptor-interacting proteins (Rachez et al, 1998). Subsequent analysis revealed that they shared at least nine proteins, and this activator-recruited cofactor complex (TRAP/DRIP/ARC) is part of a large composite coactivator complex used by a variety of transcription factors for the regulation of certain target genes. Such transcription factors include sterol regulatory element-binding protein (SREBP), nuclear factor- κ B (NF- κ B), and VP16 (Sun et al, 1998; Gu et al, 1999; Ito et al, 1999; Naar et al, 1999; Ryu et al, 1999).

In summary, the TATA box tells where RNA polymerase binds and where the initiation of transcription is to start and the hormone response element regulates how frequently it is to be transcribed when it is bound to a hormone receptor. This is accomplished by the presence of certain cofactors in the TRAP/DRIP complex. Because the hormone response element of DNA sequence has been shown to be independent of its position or its orientation, it resembles what has been called the *transcription enhancer element* that has been found in many other types of genes. The hormone response element section can vary in its location upstream from the initiation of the gene from -20 to -6000 for various different types of

hormones. With the steroid hormones, it appears to reside about -140 nucleotides upstream from the initiation site. For example, in the glucocorticoid receptor recognition element, the site for glucocorticoid receptor recognition is approximately -140 and contains a sequence of nucleotides of AAAATGGAC. Deletion mapping experiments have indicated that the receptor-binding domain located in the hormone response element is indeed required for receptor binding and is necessary for steroid-mediated control of transcription.

Once the DNA is transcribed into mRNA, a series of adenine units are added to the end (called the *poly-A tail*) and then the mRNA is cut and spliced on small nuclear particles (called *spliceosomes*) located on the nuclear matrix, and this splicing removes the intron portion of the message. The final mRNA is shipped out of the nucleus, believed to occur on the structural components of the nuclear matrix, and passes through the pore complexes of the nucleus and out to the ribosomes where the mRNA is then translated into protein product, a step termed *translation*. The proteins have specific amino acid sequences that instruct the cell where to ship the protein in relation to secretory granules or to the membrane area. The protein can also be modified after translation by the subsequent addition of carbohydrates to become glycoproteins or to be phosphorylated by kinases. Under appropriate signals, such as neurologic control, secretory proteins can then be excreted into the lumen of the prostate. This is a process that occurs when secretory proteins of the prostate and seminal vesicles are formed into the ejaculate. A schematic example of this process is shown in Figure 102-7, and such a system would include PSA and acid phosphatase as well as many other protein products that are regulated in their synthesis by androgens through receptor interactions.

During embryonic development, the AR appears first in the mesenchyme of both the rat ventral prostate and seminal vesicles and a few days later in the epithelial cells, but it is unknown what regulates this timing. **In the development of the seminal vesicles and the wolffian duct, testosterone appears to be the primary androgen in glandular development, and in the ventral prostate that forms from the urogenital sinus the androgen is primarily DHT.** Both testosterone and DHT can bind to the AR; however, on a molar basis, DHT is 3 to 10 times more potent. This decrease in potency of testosterone is believed to be caused by the rapid off rates of the testosterone once it is bound so that equilibrium results in less receptor occupancy compared with DHT at similar tissue levels. A report indicates that in some cases, AR-mediated transcriptional regulation can occur even in the absence of direct interaction of the AR with the specific androgen response elements (Kallio et al, 1995). The report stated that the ARs are able to elicit both transrepression and transactivation without interacting directly with the specific DNA elements. This may indicate that the AR can bind to regulatory units within the transcription factors and thus alter their properties even in the absence of direct DNA binding to an androgen response element.

The next part of this discussion is focused on the structure of the nucleus, where the genetic information of the genes, the AR interactions, and the mRNA processing occur and are integrated. This is within a highly ordered structure of the nucleus that is determined by a residual scaffolding framework, called the *nuclear matrix*, which provides three-dimensional organization to both the nucleus and the DNA.

Role of the Nuclear Matrix in Androgen Action

The DNA may be identical in every cell of different tissues in the body, but it appears to be organized in a different three-dimensional array in different cell types. This spatial organization of DNA appears to be determined in part by nuclear architecture and structure dictated by the scaffolding element termed the *nuclear matrix*. Therefore, more may be required than just a steroid receptor and a DNA sequence with an androgen response element to determine the high tissue specificity of androgen hormone action. It may require regulation of DNA conformation and three-dimensional structure. There is strong evidence to support the belief that

structural components of the nucleus may organize the DNA into different topologic constraints that permit specific steroid receptor interactions themselves. It is also believed that these structural modifications of DNA topology may be an integral part of differentiation. The nuclear matrix has been proposed to be an important structural element in this type of DNA organization (Getzenberg et al, 1990; Boccardo et al, 2003). The matrix facilitates the location of target genes and their conformation and facilitates their cointeraction with steroid receptors. Barrack and Coffey first showed that the nuclear matrix is a major target for androgen and ER binding (Barrack and Coffey, 1980; Barrack, 1987). Because the matrix has been implicated in many important nuclear events, it would provide an ideal target for androgen action. The nuclear matrix has been defined as the dynamic structural subcomponent of the nucleus that directs the functional organization of DNA into loop domains and provides sites for the specific control of nucleic acids (Nelson et al, 1986; Getzenberg et al, 1990). Conceptually, it can be viewed as the nuclear equivalent to the cytomatrix or cytoskeleton. The nuclear matrix contains residual nuclear elements, including the pore complex lamina, the residual nucleolus, and an internal ribonucleoprotein particle network attached to a dynamic fibrous protein mesh (Berezney and Coffey, 1977). The nuclear matrix may be isolated by sequential extractions using nonionic detergent, brief digestion with DNase I, and a hypertonic salt buffer wash. The residual nuclear matrix structures represent only 15% or less of the original total nuclear mass. More than 98% of the DNA, 70% of the RNA, and 90% of the nuclear proteins have been extracted, and the remaining structure is essentially devoid of histones and lipids.

The nuclear matrix has been implicated as an important structural component in a wide variety of biologic functions. There are approximately 50,000 DNA loop domains in a nucleus, each containing about 60 kilobase pairs of DNA, and these loops are attached at their bases to the nuclear matrix (Pardoll et al, 1980; Vogelstein et al, 1980; Luke and Coffey, 1994). This loop organization is maintained during interphase and throughout metaphase (Nelson et al, 1986). Topoisomerase II, an enzyme that modulates DNA twisting and topology, is associated with the nuclear matrix and the mitotic chromosome scaffold. Many studies with a wide variety of systems have demonstrated that active genes are associated with the nuclear matrix, whereas transcriptionally inactive genes are not close to the matrix. This location of active genes on the matrix provides evidence that the matrix plays an important organizing role in differentiation, placing genes in different configuration.

Androgens can activate DNA synthesis and cell replication in target tissues. The nuclear matrix also serves an important role in DNA replication. The matrix contains fixed sites for DNA synthesis (Pardoll et al, 1980) located at the base of the DNA loop. During DNA synthesis the DNA loop domains are reeled down through the attached replicating complex that is fixed on the matrix. Therefore, the DNA replication fork, DNA polymerase, and newly replicated DNA have been shown to be associated with the nuclear matrix. It is easy to visualize how hormone action and alteration in the nuclear matrix structures could impinge on the androgen regulation of DNA synthesis and growth in a prostate cell.

The nuclear matrix is also associated with mRNA synthesis during transcription. Ciejek and colleagues (1982) observed that more than 95% of the unprocessed mRNA precursor for ovalbumin is associated with nuclear matrix of the chick oviduct. When the intron portions of the RNA were spliced out, the mature mRNA was released from the nuclear matrix. This led them to suggest that the nuclear matrix is involved in RNA processing. Marriman and van Venrooij (1985) reported that all RNA cleavage products and RNA processing intermediates are firmly bound to nuclear matrix. Once again, alterations in nuclear matrix structures with steroid receptor interactions could alter important steps in transcription and RNA processing. The nuclear matrix contains the attachment sites for the small nuclear ribonucleoprotein particles that are part of the nuclear spliceosome system central to the nuclear processing of RNA to the final mRNA, which is transported out to the cytoplasm to be translated.

Ahmed and colleagues have carried out an extensive series of studies of the phosphorylation of the nuclear matrix and related proteins in the ventral prostate of the rat after androgen stimulation and withdrawal (Ahmed and Goueli, 1987; Ahmed et al, 1993; Tawfic et al, 1993, 1994). They have shown that the nuclear matrix can be phosphorylated by casein kinase 2 (CK-2). One of the targets of this phosphorylation is nucleolin, which is an abundant nucleolar phosphoprotein involved in the synthesis of ribosomal DNA and exquisitely regulated by androgens (Tawfic et al, 1994). Another important protein in nucleolar function that is required for growth is B23, which is also regulated by CK-2 (Tawfic et al, 1993).

In summary, the nuclear matrix is an important structural modulator of nuclear regulation and is an ideal target for hormonal regulation. Indeed, the nuclear matrix is a major site of steroid hormone receptor binding (Barrack and Coffey, 1982; Donnelly et al, 1983; Wilson and Colvard, 1984; Alexander et al, 1987; Barrack, 1987; Metzger and Korach, 1990; Luke and Coffey, 1994). In the prostate, more than 60% of all nuclear ARs are associated with the nuclear matrix (Barrack and Coffey, 1982). The matrix is also a target for many other types of regulatory interactions, including the nuclear products of oncogenes and viral proteins that can also induce growth regulation similar to hormone-induced growth. For example, the nuclear matrix is reported to be a cellular target for the retrovirus Myc oncogene protein and the polyoma large T antigen. All of these transformation proteins that bind to the nucleus are believed to be early molecular events in carcinogenesis or transformation. Therefore, the observation that ARs interact with the matrix has precedence with the matrix as a common target in factors that regulate cell structure and function.

KEY POINTS: ANDROGEN RECEPTOR STRUCTURE AND FUNCTION

- The AR is a ligand-activated transcriptional regulator that on binding to androgen dissociates from chaperonins, is actively modified by a variety of methods to an active stage, is actively translocated to the nucleus, and associates first with pioneering factors that direct where in the chromatin the receptor will function and then associates with a large number of coactivators and repressors to regulate target gene expression.
- The transport of the AR is reciprocal, which is to say that it is both localized to the nucleus and actively transported out of the nucleus.
- The AR binds to DNA target sequences as a dimer, which can be direct or inverted repeats; however, the receptor always binds with the same orientation.
- The regulation of the AR appears to be one of the most important "gatekeepers" of prostate development and physiology.

PROSTATIC SECRETIONS AND PROTEINS

Prominent, Nonpeptide Components of Prostatic Secretions

The seminal plasma is formed primarily from the secretions of the sex accessory tissues, which provide a suitable environment for survival and function of spermatozoa. The sex accessory tissues include the epididymis, ampullae, seminal vesicles, prostate, Cowper (bulbourethral) gland, and glands of Littre. The average volume of the normal human ejaculate is approximately 3 mL, ranging from 2 to 6 mL, and it has two components: spermatozoa and seminal plasma. Spermatozoa, which represent less than 1% of the total ejaculate, are present in the range of 100 million/mL. The major contribution to the volume of seminal plasma (average 3 mL) comes from the seminal vesicles (1.5 to 2 mL), from the prostate (0.5 mL), and from the Cowper gland and glands of Littre (0.1 to 0.2 mL). During ejaculation the secretions of these glands are released in a sequential manner (Amelar, 1962;

Amelar and Hotchkiss, 1965; Tauber and Zaneveld, 1976; Zaneveld and Tauber, 1981). The first fraction of the human ejaculate is rich in sperm and prostatic secretions, such as citric acid. The level of fructose, which represents a major secretory product of the seminal vesicles, is elevated in the later fraction of ejaculate. More recently, seminal albumin was measured in seminal plasma and the authors demonstrated an association with sperm morphology but not several other semen parameters (Elzanaty et al, 2007). The overall chemical composition of normal human and rodent prostatic secretions and seminal plasma has been widely studied, and the results have been summarized in excellent reviews (Mann and Mann, 1981; Zaneveld and Tauber, 1981; Aumuller and Seitz, 1990; Daniels and Grayhack, 1990; Chow et al, 1993; Gonzalez et al, 1993; Elzanaty et al, 2007). An analysis of expressed prostatic secretions in a small cohort of men revealed that citrate, myo-inositol, and spermine metabolite measurements could potentially differentiate controls from men with prostate cancer (Serkova et al, 2008), with tissue analysis also suggesting that spermine and citrate can distinguish benign from cancerous prostate (Giskeødegård et al, 2013).

In relation to other body fluids the seminal plasma is unusual because of its high concentrations of potassium, zinc, citric acid, fructose, phosphorylcholine, spermine, free amino acids, prostaglandins, and enzymes (most notably acid phosphatase, diamine oxidase, β -glucuronidase, lactate dehydrogenase (LDH), α -amylase, PSA, and seminal proteinase).

Citric Acid

One of the major anions in human seminal plasma is citrate (mean, 376 mg/dL), which is present in the range of 20 mM or 60 mEq/L. This is compared with the chloride ion (155 mg/dL) at 40 mM. Citrate is a potent binder of metal ions, and the seminal plasma concentration of citrate, 20 mM, is comparable to that of the total divalent metals at 13.6 mM (calcium, 7 mM; magnesium, 4.5 mM; zinc, 2.1 mM). Prostatic citrate levels approximate 15.8 mg/mL (Zaneveld and Tauber, 1981), and the values for seminal vesicle citric acid secretions are almost 100-fold less, being only 0.2 mg/mL. Citric acid is formed in the prostate at 100 times higher concentration than is seen in other soft tissues (e.g., prostatic tissue, 30,000 nmol/g; other tissues, range of 150 to 450 nmol/g). The concentration of citrate in the ejaculate is 500 to 1000 times higher than that in the plasma. Prostatic secretory epithelial cells form citrate from aspartic acid and glucose. The high concentrations within the prostate result partly from the inability of the prostate cell mitochondria to oxidize citrate readily once it is formed; therefore, the rate of citrate synthesis far exceeds the rate of citrate oxidation (Costello and Franklin, 1989, 1994; Kavanagh, 1994).

Fructose

The source of fructose in human seminal plasma is the seminal vesicles (Mann and Mann, 1981). Patients with congenital absence of the seminal vesicles also have an associated absence of fructose in their ejaculates (Phadke et al, 1973). The seminal vesicle secretion contains smaller amounts of other free sugars such as glucose, sorbitol, ribose, and fructose, and these sugars usually amount to less than 10 mg/dL. In comparison, the concentration of the reducing sugar fructose is approximately 300 mg/dL in human seminal secretion, and it has a level of 200 mg/dL in seminal plasma. The fructose of the seminal plasma appears to provide an anaerobic and an aerobic source of energy for the spermatozoa (Mann and Mann, 1981) and has been indirectly linked to forward sperm motility and seminal viscosity (Gonzalez et al, 1993; Fabiani et al, 1995).

Fructose levels are under androgenic regulation, but many factors, such as storage, frequency of ejaculation, blood glucose levels, and nutritional status, can also affect seminal plasma concentration (Mann and Mann, 1981); these considerations may account for the wide variations encountered in different semen samples from the same patient. Furthermore, plasma levels of androgens do not always correlate with seminal plasma fructose

levels; therefore these levels are not a reliable index of the androgenic state of the subject. Seminal fructose levels have also been proposed to be under sympathetic control (Lamano-Carvalho et al, 1993; Kempinas et al, 1995).

Polyamines

Polyamines are the most basic (positively charged) small organic molecules in nature. They occur ubiquitously in tissues at high concentrations and are believed to be involved in diverse physiologic processes that share a relationship to cell proliferation and growth. Indeed, polyamines can serve as growth factors for cultured mammalian cells and bacteria and as inhibitors of enzymes, including protein kinases.

The exact role of polyamines at the molecular level still eludes science, but they represent important biologic compounds and are found at high levels in the ejaculate. Polyamines may affect the gating and transport of substances through membrane channels. From a clinical perspective, polyamines (spermidine and spermine) have been investigated as markers of androgen deprivation therapy among men with advanced-stage prostate cancer (Cipolla et al, 1994). Other researchers (Heston, 1991; Kadmon, 1992; Madhubala and Pegg, 1992; Love et al, 1993) have investigated the role of polyamines in the pathophysiology of prostate cancer. The first and rate-limiting step in polyamine synthesis within the prostate is controlled by the enzyme ornithine decarboxylase (ODC). ODC gene expression has been demonstrated to be increased in BPH tissue (Liu et al, 2002). ODC can be inhibited by difluoromethylornithine (DMFO), which in turn inhibits polyamine synthesis. DMFO has been proposed as an agent for chemoprevention of prostate cancer (Kadmon, 1992).

Spermine levels in normal human seminal plasma range from 50 to 350 mg/dL and originate primarily from the prostate gland, which is the richest source of spermine in the body. Spermine $[\text{NH}_2-(\text{CH}_2)_3-\text{NH}-(\text{CH}_2)_4-(\text{CH}_2)_4-\text{NH}-(\text{CH}_2)_3-\text{NH}_2]$ is a basic aliphatic polyamine and, because of its four positive charges, binds strongly to acidic or negatively charged molecules such as phosphate ions, nucleic acid, and phospholipids. When semen is allowed to stand at room temperature, acid phosphatase enzymatically hydrolyzes seminal phosphorylcholine to form free inorganic phosphate ions, which then interact with the positively charged spermine and precipitate as large, translucent salt crystals of spermine phosphate. Polyamines can also form amide bonds and make their covalent addition to protein carboxylic groups (Williams-Ashman et al, 1975), and this modification may be involved in regulatory function.

There has been much interest in spermine and other related polyamines, such as spermidine and putrescine, because of the rapid and dramatic changes in levels and ratios associated with many types of cells that have been induced into growth. Williams-Ashman and colleagues have investigated in detail the biosynthesis and regulation of polyamines in the male reproductive tract and have characterized the enzymatic reactions that progress from ornithine to putrescine to spermidine to spermine (Williams-Ashman et al, 1969, 1972, 1975). Polyamines are oxidized enzymatically by diamine oxidase (present in the seminal plasma) to form highly reactive aldehyde compounds that can be toxic to both sperm and bacteria (Le Calvé et al, 1995). The formation of these aldehyde products produces the characteristic odor of semen. It is also possible that these aldehydes or polyamines may, themselves, protect the genitourinary tract from infective agents. Relationships between spermine levels in seminal plasma and sperm count and motility have also been suggested (Stamey et al, 1968; Fair and Parrish, 1981; Fair et al, 1993; Le Calvé et al, 1995). Like citrate, spermine can also be quantified within prostatic tissue by magnetic resonance spectroscopy (van der Graaf et al, 2000).

Phosphorylcholine

Other positively charged amines are at high concentrations in the ejaculate, including choline and phosphorylcholine, which

are usually found as components of lipid or as lipotropic factors. The semen of mammals is rich in choline $[(CH_3)_3-N^+-(CH_2)_2-OH]$. In humans, phosphorylcholine predominates, whereas in most other species much higher levels of α -glycerylphosphorylcholine are present, often exceeding 1 g/dL of seminal plasma. Seligman and associates (1975) have demonstrated that phosphorylcholine is a highly specific substrate for PAP, which is also active in seminal plasma. The result of this enzymatic activity is the rapid formation of free choline in the first ejaculate. In contrast, α -glycerylphosphorylcholine is secreted primarily in the epididymis and is not readily hydrolyzed by acid phosphatase. For these reasons, Mann and Mann (1981) have suggested that the level of α -glycerylphosphorylcholine can be used as an index for assessing the contribution of the epididymal secretion to the ejaculate. The secretion from the epididymis is also under androgenic control. The function of these choline compounds is unknown; it appears that they are not metabolized by spermatozoa, nor do they affect the respiration of the sperm (Dawson et al, 1957).

Prostaglandins

The richest sources of prostaglandins in the human are the seminal vesicles (Pourian et al, 1995). Prostaglandins are present in seminal plasma at a total concentration of 100 to 300 μ g/mL. Von Euler (1934) proposed the name prostaglandins for the active components in seminal plasma in the belief that they originated from the prostate gland, but Eliasson (1959) established that the primary source of prostaglandin is the seminal vesicles, not the prostate; however, the original name has survived. Prostaglandins have a wide distribution in mammalian tissues but at much lower concentrations than in the seminal vesicles (Vane and Botting, 1995).

There are more than 90 different prostaglandins present in the human, with 15 prostaglandins present in human semen, and they are all 20-carbon hydroxy fatty acids with a cyclopentane ring having two side chains; as such, they are derivatives of prostanoic acid. The 15 types of prostaglandins within the prostate are divided into four major groups, designated A, B, E, and F according to the structure of the five-membered cyclopentane ring. Each of these groups is further subdivided according to the position and number of double bonds in the side chain (therefore, PGE₃ indicates prostaglandins of E type with three double bonds in the side chain). The E group of prostaglandins is the major component in the male reproductive tract, whereas the F group predominates in the female system. Fuchs and Chantharaski (1976) have summarized the reported levels of human seminal plasma prostaglandins and report the following mean values (μ g/mL): PGE₁, 20; PGE₂, 15; (PGE₁ + PGE₂) – 19-OH, 100; PGA₁ + PGA₂, 9; (PGA₁ + PGA₂) – 19-OH, 31; PGB₁ + PGB₂, 18; (PGB₁ + PGB₂) – 19-OH, 13; PGF_{1 α} , 3; and PGF_{2 α} , 4.

These compounds are potent pharmacologic agents that have been implicated in a wide variety of biologic events in the male, including erection, ejaculation, and sperm motility and transport, as well as in testicular and penile contractions. In addition, prostaglandins from seminal fluid deposited in the vagina have been reported to affect cervical mucus, vaginal secretion, and sperm transport in the female genital tract. Prostaglandin E has been related to the immunosuppressive effects of seminal plasma mediated through the extracellular organelles, or “prostatosomes” (Kelly et al, 1991).

Zinc

The high level of zinc in human seminal plasma (140 μ g/mL) appears to originate primarily from secretions of the prostate gland (488 ± 18 μ g/mL) (Bedwal and Bahuguna, 1994). The prostate has the highest concentration of zinc (50 mg/100 g dry weight) of any organ. Byar (1974) has reviewed many of the early experiments and concepts related to zinc in the reproductive tract. Zinc levels are elevated or stable in BPH, whereas there is a marked decrease in zinc content associated with prostatic adenocarcinoma.

The localization of zinc-65 in the human prostate by radioautography appears to be within the epithelial cells; however, in the lateral prostate of the rat, large quantities of zinc were also associated with the stroma and particularly with the basal membrane and the elastin protein component (Chandler et al, 1977). Oral intake of zinc does not alter zinc levels in prostatic fluid.

Many physiologic roles have been postulated for zinc since the classic studies of Gunn and associates (1956, 1965), who correlated endocrine effects on zinc uptake and concentration in the prostate of the rodent. There are many important zinc-containing metallo-enzymes, but the concentration of zinc in the prostate probably exceeds that present in zinc-associated enzymes. Zinc is known to bind many proteins (Sansone et al, 1991). Johnson and associates (1969) characterized zinc-binding proteins in the prostatic secretion of the dog, on hydrolysis, as containing only eight types of amino acids. Heathcote and Washington (1973) described a zinc-binding protein in human BPH that was rich in histidine and alanine. Jonsson and colleagues (2005) suggested that one possible role of zinc in semen may be to regulate the activity of PSA by binding to semenogelins I and II and fragments thereof. There have been other studies on zinc-binding proteins from the prostate (Reed and Stitch, 1973; Fair et al, 1976), and additional information on these interesting proteins is needed.

An important role for zinc in prostatic secretion has been postulated in the studies of Fair and associates (1976), which suggest the direct role of zinc as a prostatic antibacterial factor. In the study of 36 normal men free from bacterial prostatic infections, the mean value of zinc in the prostatic secretion was approximately 350 μ g/mL, with a wide range of 150 to 1000 μ g/mL. In comparison, the prostatic fluid obtained from 61 specimens collected from 15 patients with documented chronic bacterial prostatitis had a reduction of more than 80% and averaged only 50 μ g/mL, with a range of 0 to 139 μ g/mL. The authors proposed a lower limit of normal at 150 μ g/mL. In addition, in vitro studies of free zinc ions at concentrations normally found in prostatic fluid have confirmed the bactericidal activity of zinc against a variety of gram-positive and gram-negative bacteria. However, a considerable portion of the zinc in the prostate appears to be bound to unique proteins, such as metallothionein, and it is not certain how this might alter the biologic properties of zinc (Suzuki et al, 1994, 1995). Yan and colleagues (2008) reported that assessment of decreased zinc in a normal human PREC in vitro resulted in increased single-strand DNA breaks (Comet assay) and differential expression of several genes (Affymetrix HG-U133A gene chips) involved in cell cycle progression, apoptosis, transcription, and DNA damage response and repair. Hence, a zinc deficiency may compromise DNA integrity in the prostate. In prostate cancer the ability of prostate cells to accumulate zinc is lost during disease progression and may be in part caused by the genetic and epigenetic alterations produced by zinc depletion.

Prostatic Secretory Proteins

The predominant secretory proteins of the sex accessory tissues have been reviewed (Lilja and Abrahamsson, 1988; Aumuller and Seitz, 1990; Aumuller et al, 1990; Lilja, 1993a, 1993b; Rittenhouse et al, 1998; Saedi et al, 2001; Diamandis and Yousef, 2002; Yousef and Diamandis, 2002). High-resolution, two-dimensional electrophoresis profiles of the major secretory protein markers from human ejaculate, seminal plasma, and prostatic secretions have been reported (Edwards et al, 1981; Carter and Resnick, 1982; Rui et al, 1984; Tsai et al, 1984; Dube et al, 1987; Aumuller and Seitz, 1990).

With regard to the prostate, several secretory proteins are found in abundance and have clinical significance. These include primarily PSA (human kallikrein 3 [hK3, protein; or KLK3, gene]) and human kallikrein 2 (hK2 or KLK2), but also prostate/CLK-L1 (Yousef et al, 1999; Lwaleed et al, 2004; Clements, 2008), PAP, and prostate-specific protein (PSP-94), also called β -microseminoprotein (β -MSP). Table 102-4 lists some characteristics of the major secretory proteins in the sex accessory tissues.

TABLE 102-4 Major Proteins Secreted by the Sex Accessory Tissue

PROTEIN OR GENE IDENTIFICATION	MOLECULAR WEIGHT (kD)	SEMINAL PLASMA (mg/nL)	ACTIVITY
Prostate-specific antigen (PSA) (hK3 [protein] or <i>KLK3</i> [gene])	33-36	0.70	Serine protease; arginine esterase
Human kallikrein 2 (hK2 or <i>KLK2</i>)	28.4	0.012	In vivo activation of proPSA, arginine esterase
Human kallikrein L1 (<i>KLK-L1</i>)	Unknown	Unknown	Serine protease, also in testes, breast, adrenal, uterus, thyroid, and salivary glands
Human kallikrein 11	Approximately 40	0.002-0.037	Serine protease, also in breast, ovary, and prostate
Prostatic acid phosphatase (PAP)	102-106	0.3-1.0	Phosphotyrosyl protein phosphatase
Prostate-specific transglutaminase	17	Unknown	Involved in the formation of stable, functional peptide-bound glutamine and primary amine groups
Semenogelins I and II	50, 63	2 mM*	Have chymotrypsin-like activity; inhibit PSA activity in the semen
Prostate-specific membrane antigen (PMSA)	Approximately 120	Unknown	Has a structure identical to glutamate carboxypeptidase II and folate hydrolase I; found in kidney, testis, ovary, brain, salivary gland, small intestine, colon, liver, spleen, breast, and skeletal muscle
Prostate stem cell antigen (PSCA)	Approximately 24	Unknown	A prostate cancer-associated tumor antigen Northern blot and in situ data show that PSCA is predominantly prostate specific in normal tissues and is overexpressed in greater than 80% of prostate cancers
Prostate-specific protein (PSP-94), β -microseminoprotein (β -MSP)	10.7-16	0.6-0.9	Also found in epithelial cells of antrum of stomach
Immunoglobulins	160	0.007-0.022	Human IgG
C3 complement	Approximately 178	0.018	An integral part of the complement cascade (C3 activates alternate pathway)
Transferrin	77	0.18	A plasma protein that transports iron through the blood to the liver, spleen, and bone marrow

*Only given in mM concentrations.

Table 102-5 illustrates the number of sample, median, and ranges of components of prostatic secretions among normal male reproductive parameters.

Prostate-Specific Antigen

PSA is a secreted serine protease, first demonstrated in human prostatic tissue in 1970 (Ablin and Soanes, 1970), found in seminal plasma in 1971 (Hara et al, 1971), purified from prostatic tissue in 1979 (Wang et al, 1979), measured in the serum of men in 1980 (Kuriyama et al, 1980), cloned at the gene level in 1987 (Lundwall and Lilja 1987), and widely used as a clinical marker of prostate cancer by 1988 (Seamonds et al, 1986; Chan et al, 1987; Stamey et al, 1987; Oesterling et al, 1988).

The discovery of PSA resulted from a search of the ejaculate and prostatic fluid by immunoprecipitation to find specific proteins for forensic use. In 1971, Japanese workers isolated, from the seminal plasma, a protein that was proved to be antigenically specific for semen; they reported its chemical and physical characteristics and termed it γ -seminoprotein (Hara et al, 1971). Several years later, in an attempt to develop this protein further as a forensic

marker for semen identification, γ -seminoprotein was purified from human seminal plasma. These seminal proteins, initially called γ -seminoproteins, have now been shown by sequence to be the same as PSA.

PSA is a glycoprotein acting as a serine protease of molecular weight 33 kD that contains 7% carbohydrate (Watt et al, 1986) and is found almost exclusively in the epithelial cells of the prostate (Armbruster, 1993; Rittenhouse et al, 1998). It consists of a single polypeptide chain and contains 240 amino acids and an O-linked carbohydrate side chain attached to a serine residue (Watt et al, 1986). PSA acts physiologically like a serine protease and an arginine esterase with both chymotrypsin-like and trypsin-like activity. The sequence of the protein is similar to that of other kallikreins (Rittenhouse et al, 1998) involved in prostatic cell regulatory mechanisms. Lilja (1985) and Watt and coworkers (1986) reported that one of the structural proteins of the seminal fluid, semenogelin, causes the ejaculate to clot. Semenogelin is the predominant seminal vesicle-secreted protein and one of the physiologic substrates for PSA. One possible biologic role of PSA is to lyse the clot in the ejaculate, but it is at present unknown why this clotting and lysing mechanism is important to reproductive physiology.

TABLE 102-5 Components of Prostatic Secretions

VARIABLES	N	MEDIAN	RANGE
Age (yr)	916	34	20-64
Time of sexual abstinence (days)	916	4.0	1.0-60
Semen volume (mL)	916	4.0	1.0-15
Sperm concentration ($\times 10^6$ mL ⁻¹)	916	44	0.1-568
Total sperm count ($\times 10^6$ mL ⁻¹)	916	167	0.4-2400
a (%)	916	14	0-80
b (%)	916	28	0-80
a + b (%)	916	50	0-90
c (%)	916	16	0-50
d (%)	916	33	0-100
Total a + b ($\times 10^6$ per ejaculate)	916	83	0-1200
Normal forms (%)	916	5.0	0-20
Tail defects (%)	916	11	1.0-85
DFI (%)	267	15	3.0-90
HDS (%)	267	7.0	1.0-40
NAG (mU/mL ⁻¹)	506	6.0	1.0-15
PSA (mg/L ⁻¹)	900	890	66-3400 or higher
Zinc (mmol/L ⁻¹)	900	2.0	0-7.0
Fructose (mmol/L ⁻¹)	900	14	0-39
FSH (IU/L ⁻¹)	351	5.0	1.0-45
LH (IU/L ⁻¹)	351	3.0	1.0-13
Testosterone (nmol/L ⁻¹)	351	13	3.0-31
Inhibin B (ng/L ⁻¹)	351	150	14-450
SHBG (nmol/L ⁻¹)	351	26	2.0-88

DFI, DNA fragmentation index; FSH, follicle-stimulating hormone; HDS, high DNA stainability; LH, luteinizing hormone; NAG, *N*-acetylglucosamine; PSA, prostate-specific antigen; SHBG, sex hormone binding globulin. From Elzanaty S, Erenpreiss J, Becker C. Seminal plasma albumin: origin and relation to male reproductive parameters. *Andrologia* 2007;39:60-5.

The PSA gene (*hKLK3*) is a member of a human tissue kallikrein gene family that includes *hKLK1*, *hKLK2*, *hKLK3*, and *KLK-L1* (Lundwall, 1989; McMullen et al, 1991; Berg et al, 1992; Carbin et al, 1993; Clements, 1994; McCormack et al, 1995; Rittenhouse et al, 1998; Nelson et al, 1999; Yousef and Diamandis, 2003). To date there are more than 15 different human kallikreins, with expression noted in prostate, breast, ovarian, and testicular cancers (Obiezu and Diamandis, 2005). These genes are all located on chromosome 19 (Reigman et al, 1992; Yousef et al, 1999; Yousef and Diamandis, 2003). The ectopic expression of PSA has been reported in smaller concentrations in the tissue of malignant breast tumors (Yu et al, 1994a, 1994b, 1994c), normal breast tissue, breast milk, female serum, and adrenal and renal carcinomas; however, for practical and clinical purposes, PSA is an androgen-dependent and prostate organ-specific (but not a cancer-specific) marker. A limitation of PSA as a tumor marker is demonstrated in the substantial overlap in values between benign and malignant prostate disease (Oesterling et al, 1988; Partin et al, 1990).

Most work regarding the molecular biology and biochemistry of PSA is based on extensive study of purified protein from seminal fluid in which the concentration of PSA is nearly a million-fold higher than that found routinely in serum (McCormack et al, 1995). The concentrations found in seminal plasma range from 0.5 to 5.0 mg/mL, whereas normal serum concentrations in men aged 50 to 80 years without prostatic disease range from 1.0 to 4.0 ng/mL (Catalona et al, 1991).

Prostate-Specific Antigen Derivatives

PreproPSA (261 amino acids) is processed in the endoplasmic reticulum of prostatic epithelial cells, where a 17-peptide leader sequence is cleaved to form proPSA. Seven more peptides are then cleaved from the propeptide to form the active PSA peptide (Rittenhouse et al, 1998). The cleavage of the proPSA inactive (zymogen) precursor of PSA is performed primarily in vivo by hK2 (Lilja, 1985; Villoutreix et al, 1994; Rittenhouse et al, 1998). In addition to its cleavage at the -7 residue, proPSA can also be cleaved at the -2 or -5 residue to produce catalytically inactive PSAs termed [-2]proPSA and [-5]proPSA. Finally, additional forms of inactive PSA can be formed by internal cleavages at various regions within PSA (presumably occurring in the seminal fluid after PSA is secreted). These cleaved isoforms comprise BPSA.

A small proportion of active PSA diffuses into the circulation, where it is rapidly bound or complexed by covalent attachment to protease inhibitors (most commonly, α_1 -antichymotrypsin) (Lilja et al, 1991; Stenman et al, 1991; Christensson et al, 1993; Lilja, 1993a; McCormack et al, 1995; Partin and Carter, 1996; Polascik et al, 1999). Inactive PSA can also enter the bloodstream, where it circulates in an unbound state as free PSA (fPSA).

Depending on the monoclonal antibodies used to measure serum PSA, the amounts of free and complexed PSA, as well as proPSA isoforms, can be detected. This has high clinical usefulness because the various PSA derivatives have associations with benign and cancerous prostatic tissue. In prostate cancer, the loss of gland architecture and basal cells results in a decrease in the luminal processing of proPSA to active PSA (and thus an increase in proPSA) and in addition a decrease in the processing of active PSA to BPSA (thus decreasing the amount of fPSA). Thus, increased levels of BPSA in the serum are found in benign disease, whereas proPSA (and particularly [-2]proPSA) and bound PSA are associated with prostate cancer (reviewed in Balk et al, 2003 and Tosoian and Loeb, 2010).

Human Kallikrein 2

Human kallikrein 2 (hK2 [protein] or *KLK2* [gene]) is a prostate-specific serine protease closely related to PSA (Rittenhouse et al, 1998). hK2 was first demonstrated from a low-stringency hybridization screen of a human liver genomic library in 1992, and the amino acid sequence is predicted to have 80% homology with PSA (hK3, *KLK3*) (Young et al, 1992). The striking homology between these two "prostate-specific" proteins suggested a close physiologic relationship. More recently, recombinant hK2 has been expressed and purified (Kumar et al, 1996; Mikolajczyk et al, 1998). Unlike PSA, hK2 is shown to be trypsin-like with selective cleavage at arginine residues and has a more potent (20,000-fold greater than PSA) protease activity (Mikolajczyk et al, 1998). Monoclonal antibodies to hK2 have been developed and have a low incidence of cross-reacting with PSA (Finlay et al, 1998). As mentioned earlier, physiologically, hK2 cleaves proPSA to generate the enzymatically active form of PSA in the prostate (Kumar et al, 1996). Immunohistochemical studies have shown hK2 to be increased in expression from normal to metastatic, poorly differentiated prostatic epithelium (Darson et al, 1997), and studies of hK2 in the serum of men with prostate cancer have suggested clinical usefulness for early detection of prostate cancer (Partin et al, 1999; Vickers et al, 2010).

Human Kallikrein L1

Attempts to find other novel human kallikrein-like genes on chromosome 19 have identified yet another member of the human kallikrein gene family, *KLK-L1* (Nelson et al, 1999; Yousef et al, 1999). Nelson and associates (1999) constructed a cDNA library enriched through subtraction with the cDNAs from four other normal tissues to yield an expressed sequence tag identifying a gene that they have called *prostase*. The sequence of prostase exhibits features similar to the other members of the kallikrein family. Yousef and coworkers (1999) also found *KLK-L1* in breast tissue

and demonstrated that it is hormonally regulated. Although the clinical usefulness of the members of the kallikrein gene family has not yet been determined, it is under investigation.

Human Kallikrein 11

Human kallikrein 11 (hK11) is a serine protease that shares similarities to human kallikrein 3 (hK3) or PSA with significant homologies at the levels of nucleotide and protein structure (Diamandis and Yousef, 2002). Localization of hK11 in epithelial cells of various organs has been demonstrated immunohistochemically, and hK11 has been further detected in amniotic fluid, milk of lactating women, cerebrospinal fluid, follicular fluid, and breast cancer cytosols. The highest levels of hK11 were observed in prostatic tissue extracts and seminal plasma, in which it was present at 300-fold lower levels than PSA. Elevated serum levels of hK11 were found in 60% of men with prostate cancer; the ratio of hK11 to total PSA was able to reduce the number of biopsies required, and the data were similar to those gleaned from fPSA assays (Diamandis and Yousef, 2002; Nakamura et al, 2003).

Human Kallikrein 14

Human kallikrein 14, a trypsin-like human kallikrein-related peptidase (KLK), has been shown to exert a significant and dose-dependent effect on semen liquefaction (Emami and Diamandis, 2008; Emami et al, 2008). Liquefaction of human semen involves proteolytic degradation of the seminal coagulum and release of motile spermatozoa. Several members of human kallikrein-related peptidases are implicated in semen liquefaction, functioning through highly regulated proteolytic cascades. Among these, *KLK3* (also known as *prostate-specific antigen*) is the main enzyme responsible for processing of the primary components of semen coagulum. *KLK14* recently has been identified as a potential activator of *KLK3* and other KLKs (Emami et al, 2008; Emami and Diamandis, 2008). Borgono and associates (2003) measured seminal plasma levels of *KLK14* by an enzyme-linked immunosorbent immunoassay (ELISA) in 36 human semen samples and found *KLK14* to be 0.6 to 23.6 $\mu\text{g/L}$ (mean 10.8; median 10.7 $\mu\text{g/L}$). Semenogelin I and semenogelin II are degraded by PSA to form various biologically active peptides involved in semen liquefaction and release of motile spermatozoa. Semenogelins I and II, through chelation with the excess of free zinc, are also directly cleaved by *KLK14*, in the same manner as PSA. In addition, *KLK14* has also been demonstrated to be a potential biomarker for ovarian and breast cancer (Borgono et al, 2003).

KEY POINTS: SECRETORY PROTEINS—KALLIKREINS

- Secreted prostate proteases exert a significant and dose-dependent effect on semen liquefaction
- Among the most well-studied secreted prostate proteins are hKLK3 (PSA) and a homologous protease, hK2, which functions to cleave PSA.
- PSA and its processed derivative (i.e., BPSA, fPSA, [–2]pro-PSA), as well as hK2, have various associations with benign prostatic tissue and prostate cancer and are currently being used to aid in prostate cancer screening.

Prostate-Specific Transglutaminases

Human prostate-specific transglutaminase 4 belongs to a family of enzymes that irreversibly cross-link peptide-bound glutamine residues through reactions with either lysines or primary amines such as polyamines (Dubbink et al, 1998). Transglutaminases are located throughout the body, but they are highly tissue specific. Dubbink and coworkers (1998) described a new prostate-specific transglutaminase with 35-kilobase genomic DNA and consisting of 13 exons and 12 introns. The main transcription initiation site is located 52 base pairs upstream of the translational start code. At least one

splice variant has been described, and a transglutaminase 4 gene (*TGM4*) promoter was analyzed by sequencing and transfection experiments and found at –1276 to –563. Subsequently, an Sp1 binding site (promoter) required for basal activity of *TGM4* was identified (Dubbink et al, 1999). The *TGM4* promoter was characterized by deletion mapping and mutational analysis. These researchers determined that positions between –113 and –87 were essential for core activity of the promoter. The sequences identified are binding sites for the Sp1 and Sp3 transcription factors; however, their precise role in *TGM4* regulation was not deduced from experiments described (Dubbink et al, 1999). Of importance is the fact that the major gel-forming proteins in semen, semenogelins I and II, are substrates for transglutaminase 4 (Peter et al, 1998). Esposito and Caputo (2005) reviewed the range of substrates for transglutaminases in detail and characterized the molecular basis of transglutaminase-catalyzed reactions and also assessed possible physiologic function and pathophysiologic processes resulting from such interactions. The transglutaminase for the prostate is transglutaminase 4; it weighs 77 kD, is androgen regulated, and is found extracellularly. Transglutaminases catalyze the post-translational modification of proteins by formation of polymerized cross-linkages between the γ -carboxamide group of protein-bound glutamine residues and the ϵ -amino group of protein-bound lysine residues, which results in a stabilized molecular complex. There is evidence to suggest that the biochemical affinity of transglutaminase 4 for acyl-type substrates such as kinesin proteins in protein secretions of the semen may be important for correct extrusion of transglutaminase 4 from the coagulating gland (Esposito and Caputo, 2005).

An and coworkers (1999) also described cloning of *TGM4* (human prostate-specific transglutaminase) and its promoter in the elements of –1 to –500 and also at –520 to –1400. In addition, this group applied Northern blot hybridization and reverse transcription polymerase chain reaction (RT-PCR) analysis to confirm prostatic specificity and Gleason grade-specific expression by RT-PCR and noted significant downregulation in high Gleason grade as well as in metastatic tissue extracts. From a protein perspective, Birckbichler and colleagues (2000) revealed by quantitative immunofluorescence that prostate cancer was significantly decreased compared with normal prostate and prostatitis patients, but this is in contrast to what was observed with RT-PCR results (An et al, 1999), in which the higher Gleason grade tumors tended to be significantly decreased. This discrepancy of results needs to be rectified in larger experiments comparing RT-PCR with protein expression to determine whether this is a technical problem or rather one of translation of transglutaminase 4 mRNA versus protein in the malignant disease process.

Semenogelins I and II

Semenogelin I and semenogelin II are dominant proteins in human semen coagulum that are degraded by PSA to form various biologically active peptides, which in combination with fibronectin give rise to the gel-like coagulum of newly ejaculated semen (Lilja, 1985; Malm et al, 1996; de Lamirande et al, 1997). The genes encoding semenogelins I and II are located in separate regions 11.5 kilobase pairs apart on chromosome 20. The major biologic function of semenogelin involves **capacitation**, which is defined as a series of changes in cell membranes, enzyme activities, and ion fluxes that sperm undergo as they traverse the female urogenital tract to reach the zona pellucida and fertilize the egg (de Lamirande et al, 1997). It has been demonstrated that biologically active peptides from semenogelin I and semenogelin II proteolysis scavenge superoxide anion and may affect sperm oxidase to serve as natural regulators of sperm capacitation (de Lamirande et al, 2001; de Lamirande, 2007). Semenogelins from the seminal vesicles and zinc ions from the prostate play a significant role in semen aggregation at the time of sperm ejaculation and also in sperm motility by binding to the sperm and then interacting with zinc (de Lamirande, 2007; Yoshida et al, 2008). It is of physiologic and possibly pathophysiologic importance that these major gel-forming proteins in semen, semenogelins I and II, are substrates for transglutaminase 4 (Peter

et al, 1998). Both of these proteins originate from the glandular epithelium of the seminal vesicles and are produced in high concentrations; however, in the epididymis, only semenogelin I is expressed. There is evidence by immunohistochemistry that other cell types including the vas deferens, prostate, and trachea demonstrate strong signals for semenogelins I and II, and weaker but positive signals were seen in skeletal muscle cells and in the central nervous system (Lundwall et al, 2002).

Prostate-Specific Membrane Antigen

Reviews of the biochemistry and biology of the prostate-specific membrane antigen (PSMA) in human tissues and prostate cancer surveys describe the differential regulation of the molecule, its enzymatic functions, and its potential as a biomarker for in vivo imaging, targeted therapy, and immunotherapy (Elgamal et al, 2000; Ghosh and Heston, 2004).

The gene encoding PSMA is located on chromosome 11p11-12 and codes for a type II membrane glycoprotein (molecular weight approximately 100,000 Da) with intracellular (1 to 18 amino acids), transmembrane (19 to 43 amino acids), and large extracellular (44 to 750 amino acids) domains (Israeli et al, 1994; Ghosh and Heston, 2004; Davis et al, 2005). The cDNA (2.65 kb GenBank accession number M99487) encoding PSMA was first reported by Israeli and colleagues in 1993 and its deduced amino acid sequence determined (Israeli et al, 1994). It encodes a 750-amino acid protein with a predicted molecular mass of 84 kD (excluding carbohydrates). The hydrophobic amino acids found on amino acid residues 20 to 43 suggested that this protein is a type II integral membrane protein with a small intracellular domain and a large extracellular domain (Fair et al, 1997). The promoter for PSMA has been cloned (Good et al, 1999), and PSMA has been expressed and purified from a baculovirus expression system (Lodge et al, 1999). A portion of the transmembrane domain of this protein (amino acid residues 1250 to 1700) shares 57% homology with the human transferrin receptor mRNA (Mahadevan and Saldanha, 1999). Alternative splicing variants of PSMA (PSM'-PSA' extracellular domain protein) are under investigation to better understand the clinical significance of this important membrane protein found within the prostate (Liu et al, 1997; Grauer et al, 1998; Murphy et al, 1998; Ghosh and Heston, 2004; Rajasekaran et al, 2005). PSMA has been crystallized and its structure deduced at 3.5-Å resolution. These analyses reveal a homodimer with structural similarity to the transferrin receptor, a receptor for iron-loaded transferrin that lacks protease activity (Davis et al, 2005). However, unlike the transferrin receptor, the protease domain of PSMA (glutamate carboxypeptidase II) contains a binuclear zinc site, catalytic residues, and a proposed substrate-binding arginine patch.

PSMA is strongly expressed in the prostate and is upregulated in prostate cancer and in the neovasculature of other tumors (Silver et al, 1997; Chang et al, 1999b, 2001). In the prostate there are three alternatively spliced variants of PSMA. However, only one of these isoforms (PSM' located at the 5' end of PSMA cDNA) is known to be differentially expressed in normal tissue, BPH, and prostate cancer (Elgamal et al, 2000; Rajasekaran et al, 2005). PSMA mRNA expression within prostate cancers is also in the hormone-deprived state, contrary to PSA mRNA, which often demonstrates lower, even absent expression in the hormone-deprived state (Henttu et al, 1992; Israeli et al, 1994; Wright et al, 1995; Rajasekaran et al, 2005). The association of PSMA with prostate cancer makes it a favorable target for the development of imaging molecules and therapeutics (Lupold and Rodriguez, 2004; Davis et al, 2005; Chandran et al, 2008).

Despite its name, PSMA is also expressed in many nonprostatic tissues, including the kidney, small intestine, and nervous system. PSMA in the central nervous system metabolizes the brain neurotransmitter *N*-acetyl-aspartyl-glutamate or NAAG (named NAALADase). In the intestine, PSMA is found in the proximal small intestine, where it removes γ -linked glutamates from poly- γ -glutamated folate (folate hydrolase 1), or as a carboxypeptidase, glutamate carboxypeptidase II.

Prostate Stem Cell Antigen

Reiter and coworkers (1998) identified prostate stem cell antigen (PSCA), a cell surface antigen that is expressed in the prostate (among other tissues including bladder). The PSCA gene encodes a 123-amino acid glycoprotein, with 30% homology to stem cell antigen 2 (Sca-2). Like Sca-2, PSCA is a member of the Thy-1/Ly-6 family and is anchored by a glycosylphosphatidylinositol linkage. By use of mRNA in situ hybridization, PSCA expression was localized in normal prostate to the basal cell epithelium, the putative stem cell compartment of prostatic epithelium; hence, PSCA may be a marker of prostate stem or progenitor cells. Hara and associates (2002) performed an analysis of PSA, PSMA, and PSCA mRNA level on peripheral blood by RT-PCR in 58 patients with prostate cancer and 71 patients with nonmalignant disorders. The results were 7 of 58 (12.1%) for PSA, 12 of 58 (20.7%) for PSMA, and 8 of 58 (13.8%) for PSCA; zero samples were positive for nonmalignant diseases. A hierarchical summary of prognostic value for the three biomarkers was as follows: PSCA was higher than PSA, which was higher than PSMA for RT-PCR of the 58 patients with prostate cancer. Note that in this group of patients, when the RT-PCR result was positive for PSCA the patients had a lower disease progression-free survival than with the other two biomarkers. The PSCA expression increased with higher Gleason score and cancer stage as well as with progression to metastasis and may be a useful biomarker for staging of prostate cancer (Hara et al, 2002). Han and associates (2004) performed immunohistochemistry analysis of PSCA by a 246-patient tissue microarray; the results revealed that a PSCA staining intensity of 3.0 correlated with adverse prognostic features including Gleason score of 7.0 ($P = .001$), seminal vesicle invasion ($P = .005$), and capsular involvement ($P = .033$). However, after multivariate analysis, PSCA did not hold up as an independent predictor of PSA recurrence. Zhigang and Wenly (2004) studied BPH, low-grade prostatic interepithelial neoplasia (LGPIN), high-grade prostatic interepithelial neoplasia (HGPIN), and prostate cancer at the tissue level by immunohistochemistry and at the mRNA level by in situ hybridization. In BPH and LGPIN the staining of PSCA protein and mRNA was weak or negative and less intense and uniform than in HGPIN and prostate cancer. There was moderate to strong PSCA protein as well as mRNA expression in 8 of 11 (72.7%) HGPIN and in 40 of 48 (83.4%) prostate cancer specimens that were examined by immunohistochemistry and in situ hybridization analyses. When the prostate cancer specimens examined by immunohistochemistry and in situ hybridization analyses were compared with BPH (20%) and LGPIN (22.2%) samples, the results were statistically significant ($P < .05$, respectively). The expression level of PSCA increased with high Gleason grade, advanced stage, and progression to androgen independence ($P < .05$, respectively). In addition, in this study, protein immunostaining and in situ hybridization mRNA stain showed a high degree of correlation between PSCA protein and mRNA overexpression in prostate cancer, supporting the potential of PSCA as a prognostic biomarker. Clearly, the value of this protein to the biology of prostate epithelial tissue morphogenesis and also as a new biomarker for diagnosis and treatment of prostate cancer is yet to be realized.

The potential use of PSCA, a membrane surface antigen that is highly expressed in the prostate, as a novel prostate targeting medical device for diagnostics (blood immunoassays or medical imaging) and therapy (vaccines or immunotherapy) is currently being actively studied (Olafsen et al, 2007; Raff et al, 2009). Here is another unique opportunity to use prostate developmental knowledge as a possible tool to manage prostate cancer because of its amplification during carcinogenesis.

Prostatic Acid Phosphatase

Acid phosphatase activity is more than 200 times more abundant in prostatic tissue than in any other tissue and is the source of the high levels of acid phosphatase in ejaculate. Phosphatase enzymes hydrolyze many types of organic monophosphate esters to yield

inorganic phosphate and alcohol. Many phosphatase enzymes exhibit optimal activity *in vitro* in the acid (pH 4 to 6) or alkaline (pH 8 to 11) ranges and are thus classified broadly as either acid or alkaline phosphatase.

Acid phosphatase activity may be further defined by factors that inhibit its enzymatic activity. For example, erythrocyte acid phosphatase is particularly sensitive to inhibition by 0.5% formaldehyde or copper ions (0.2 mM), whereas PAP activity is far more sensitive to inhibition by fluoride ions (1 mM) or L-tartrate (1 mM).

Osteoclasts are also a rich source of tartrate-insensitive acid phosphatase. Minor elevations in serum acid phosphatase levels can accompany Paget disease, osteoporosis, nonprostatic bone metastasis, and other conditions of increased bone resorption as well as metastatic prostate cancer. All acid phosphatases hydrolyze a wide range of natural and synthetic phosphomonoesters, and this has provided a wide variety of assay systems and the expression of different units of activity, depending on the assay. These synthetic substrates include, in part, phenylphosphate (Gutman and Gutman, 1938); phenolphthalein phosphate; paranitrophenyl phosphate, also called *Sigma 104*; and thymolphthalein phosphate (Roy et al, 1971). The specificity of these substrates varies with the type and source of acid phosphatase; it appears that thymolphthalein phosphate may be the most specific substrate for assaying serum levels of prostate-specific acid phosphatase, but specific antibodies are now available for immunoassays. Interest in acid phosphatase assays in serum as a measure of prostate cancer metastasis before definitive therapy has decreased with the availability of the more sensitive and specific PSA assay (Burnett et al, 1962).

The natural substrate for PAP may be phosphorylcholine phosphate, which is rapidly hydrolyzed in the semen (Seligman et al, 1951). The biologic functions of this enzyme and its reactions are not known, but it is of interest that PAP can hydrolyze protein tyrosine phosphate esters, natural products of many oncogene protein tyrosine kinases (Li et al, 1984; Lin and Clinton, 1986). By magnetic resonance spectroscopic techniques, it has been shown that the ratio of intracellular choline to citrate levels within the prostate can help differentiate normal from cancerous prostatic tissue (Scheidler et al, 1999). Further clinical testing is required before this finding will influence clinical practice. It is unknown whether acid phosphatase is a regulatory factor in the tyrosyl protein kinase systems that are so essential as signaling mechanisms in growth factor function.

Human PAP is a glycoprotein dimer of molecular weight 102,000 and contains about 7% carbohydrate by weight, composed of 15 residues per mole of neutral sugars (fructose, galactose, and mannose), 6 residues per mole of sialic acid, and 13 residues of N-acetylglucosamine (Chu et al, 1977). The protein can be dissociated into two subunits of 50 kD. The activity of the purified human enzyme is 723 U/mg with α -naphthyl phosphate, and the seminal plasma contains 0.3 to 1 g/L or 177 to 760 U/mL. The high enzymatic activity of PAP is not characteristic of accessory tissues in many other species; the level is 1000 times higher per gram of tissue in the human prostate than in the rat prostate. The clinical aspects of PAP were reviewed by Romas and Kwan (Lowe and Trauzzi, 1993; Romas and Kwan, 1993).

Prostate-Specific Protein 94 (β -Microseminoprotein and β -Inhibin)

A major, cysteine-rich, nonglycosylated 16-kD protein that contains 94 amino acids has been found in prostatic secretions and named *prostate-specific protein 94* (PSP-94); it is one of the three predominant proteins secreted in the prostate glands and found in seminal fluids along with PSA and PAP. This protein had previously been designated β -inhibin and also β -MSP (Dube et al, 1987; Ulvsback et al, 1989). Transcripts of mRNA for this protein have also been identified in nongenital tissues (Ulvsback et al, 1989). The human gene for PSP-94 has been mapped to chromosome 10 (q11.2), and there are three glucocorticoid response elements and one estrogen response element in the promoter region of the first intron.

Based on these observations the gene is likely regulated by hormones in humans (Nolet et al, 1991; Ochiai et al, 1995) because this also was reported in studies of the rat lateral prostate (Kwong et al, 2000). Also, Valtonen-Andre and associates (2008) demonstrated that in young, healthy males the PSP-94 levels in the serum correlate well with those in the seminal plasma ($r = 0.50$, $P < .001$). An automated immunoassay was performed with an AutoDELFIA 1235 (Wallac) and produced median values of PSP-94 in 205 young men that were 12 mg/L (2.5th to 97.5th percentile, 4.9 to 26 mg/L) in serum and 0.53 g/L (2.5th to 97.5th percentile, 0.13 to 2.0 g/L) or 1.8 mg (2.5th to 97.5th percentile, 0.32 to 6.6 mg) in seminal plasma. These data provide a solid basis for evaluation of this biomarker both in healthy men and in those with prostate cancer.

One of the main biologic functions of PSP-94 is the inhibition of follicle-stimulating hormone (Garde et al, 1999). Whereas follicle-stimulating hormone is made by the pituitary gland, the prostate has been shown to be an extrapituitary source of follicle-stimulating hormone. There are follicle-stimulating hormone receptors in the prostate, and it appears that an autocrine or paracrine regulation of this hormone influences prostate epithelial proliferation (Ben-Josef et al, 1999; Porter et al, 2001). Also, Chan and colleagues (1999) used *in situ* hybridization to study expression of PSP-94 in human prostates. They found that fetal prostate at 6 to 7 months synthesizes PSA and PAP but not PSP-94, and this observation appears to relate to the development of the prostate gland. Zonal anatomic distribution of PSP-94 in the adult prostate demonstrated that the protein is expressed mostly in the acini of the peripheral zone rather than the central or transitional zones. Anahi Franchi and associates (2008) studied the PSP-94 and its potential interaction with human spermatozoa and its possible role in fertility. Using purified PSP-94, they demonstrated a specific interaction at the sperm surface. Also, using dual-antibody ELISA technology, the authors noted that of 62 patients being assessed for fertility, fertile men had a lower concentration of the protein than subfertile men and suggested that semen quality may be affected by the concentrations of PSP-94. **Another function of PSP-94 may be to interact directly with spermatozoa in a manner that can affect the quality of sperm structure and function.**

In the area of cancer, Chan and coworkers (1999) found that PSP-94 expression is markedly downregulated with increasing Gleason grade of prostate cancer. Furthermore, Shukeir and coworkers (2003) demonstrated a significant decrease in growth of the highly metastatic Dunning R3327 subline MatLyLu rat prostate model transfected with parathyroid hormone-related protein by treatment with varying doses of commercial PSP-94 purified from human seminal plasma (0, 0.1, 1.0, and 10 μ g/kg/day). Serum levels of parathyroid hormone-related protein and calcium were used to monitor the efficacy of treatment with PSP-94. **Hence, PSP-94 is an effective inhibitor of hormone-independent, late-stage prostate cancer metastasis in this Dunning MatLyLu animal model.** The PSP-94 molecule has not yet been crystallized; however, Joshi and Jyothi (2002), in a computer-simulated molecular model, have predicted its structure and calculated its binding activity and related biologic activity (follicle-stimulating hormone inhibition) and immunogenic properties. Using a three-dimensional structure constructed by nuclear magnetic resonance (NMR), Ghasriani and associates (2006, 2009) have shown the PSP-94 molecule to consist of two distinct domains that form a rather extended structure. The two domains are connected to each other by the peptide backbone, one disulfide bond, and interactions between the amino and carboxyl termini and are oriented to give the molecule a rather extended structure. In addition, Ghasriani and associates (2009) have demonstrated the specific molecular interactions of the PSP-94 with cysteine-rich secretory protein 3 (CRISP-3) by applying multidimensional NMR. The CRISP proteins are ubiquitous among organisms and snake venoms, and they are reported to be calcium ion channel blockers; however, the relevance of these observations of protein-protein interactions to seminal plasma is yet to be determined.

Protein C Inhibitor

Human semen contains several enzymes and inhibitors of the hemostatic coagulation system (Lwaleed et al, 2004; Fernandez and Heeb, 2007). In human semen, PSA exists as a molecular complex with protein C inhibitor (PCI), and the latter provides some inhibitory consequences for actions of PSA. The predominant structural proteins of coagulated semen are those proteins secreted by the seminal vesicle including semenogelins I and II and fibronectin, and these proteins remain stable in the seminal vesicle's secretions for up to 20 hours at 37°C but rapidly cleave into small peptides on mixing with the proteases (e.g., PAP, hKLK2 [PSA], hKLK3, hKLK14) of prostatic secretion (Lwaleed et al, 2004; Fernandez and Heeb, 2007). The human PCI gene is located in chromosome 14q32.1 and is a serine protease inhibitor that corresponds to a region containing the genes of related serpins (SERPINA5) (Suzuki et al, 1987; Fernandez and Heeb, 2007; Suzuki et al, 2007). PCI is a heparin-dependent inhibitor of activated protein C (APC) that is immunologically and functionally identical to a heparin-dependent urokinase inhibitor (plasminogen activator inhibitor type 3). PCI also inhibits several other blood coagulation and fibrinolytic factors (e.g., FXa, FXI, plasma kallikrein) (Lwaleed et al, 2004; Espana et al, 2007; Fernandez and Heeb, 2007; Suzuki et al, 2007). Suzuki and associates (2007) also demonstrated that digestion of human seminal coagula with PSA releases PCI and PSA-PCI complex from the coagula into the soluble phase, suggesting the presence of active PCI within the semen coagula. PCI then forms a "ternary protein complex" with PSA and semenogelin II in the seminal plasma. The binding of semenogelin II to PSA and PCI is influenced by the molecular microenvironment, including pH, ionic strength, heparin, negatively charged dextran sulfate, divalent cations, and particularly by zinc. These observations suggest that binding of PCI to semenogelins in seminal vesicles regulates the PSA-catalyzed degradation of semenogelins in seminal plasma; the complex formation among PCI, PSA, and semenogelins is modulated by several factors in seminal plasma. Espana and colleagues (2007) determined that PCI is secreted at very high levels in the seminal vesicles in an active form and also occurs in high concentrations in the seminal plasma. The concentration of PCI in 40 seminal plasma samples ranged from 2.2 to 3.7 mM (i.e., about 220 mg/L), and 45% of the seminal PCI was functionally active when assayed immediately after ejaculation. Notably, infertile men had significantly decreased seminal PCI levels (0.6 to 3.2 mM). However, the concentration of PSA in seminal plasma far exceeds the capacity of PCI to inhibit this molecule and hence the biologic role of PCI in seminal plasma. Espana and colleagues (2007) used purified PCI to assess several functional aspects of PCI, and evidence indicated that PCI is involved in human reproduction at several key steps, including fertilization. Hence, PCI is abundant in the seminal fluid and it plays a key role in the interaction among semenogelins, PSA, and likely other proteins in semen, resulting in protein-protein interactions critical to semen coagulation and liquefaction. A balance of seminal fluid coagulative proteins, active enzymes, and metabolites is required to effect sperm motility and successful fertilization (Lwaleed et al, 2004; Espana et al, 2007; Fernandez and Heeb, 2007; Suzuki et al, 2007).

Leucine Aminopeptidase

Aminopeptidases hydrolyze the amino-terminal amino acid from small polypeptides. Leucine aminopeptidases are particularly active against the substrate L-leucyl-glycine, and some of these enzymes are referred to as *arylamidases* because the optimal substrate is L-leucyl- β -naphthylamine. The human prostate is rich in the arylamidase type of leucine aminopeptidase, with a presence in prostatic fluid of 30,000 units/mL.

Leucine aminopeptidase is a product of the epithelial cells of the prostate (Niemi et al, 1963) and is secreted into the lumen of the acini (Kirchheim et al, 1964; Vafa et al, 1993). Rackley and associates (1991) demonstrated that extracts from prostatic carcinoma

contained less leucine aminopeptidase activity than did tissue obtained from BPH.

Lactate Dehydrogenase

The isoenzyme ratios of LDH in human semen may be altered in a patient with prostate cancer (Oliver et al, 1970; Grayhack et al, 1977). LDH (molecular weight 150 kD) is composed of four subunits (each of 35 kD) of only two different types of proteins, denoted M and H. The LDH of muscle has four M units, and that of heart has four H units. Five isoenzymes of LDH can be found in tissues with a four-subunit composition as follows: LDH I, MMMM; LDH II, MMMH; LDH III, MMHH; LDH IV, MHHH; and LDH V, HHHH. The M and H subunits appear to be the same in all tissues, but the amounts of LDH I to V can vary. Denis and Prout (1963) observed increased levels of LDH IV and V in prostate cancer tissue. Several investigators have observed elevated ratios of LDH V/LDH I in human prostate cancer (Elhilali, 1968; Oliver et al, 1970; Flocks and Schmidt, 1972).

Immunoglobulins, C3 Complement, and Transferrin

There are many reports establishing the presence of Igs in human seminal plasma (Liang et al, 1981; Gahankari and Golhar, 1993). It is possible to measure levels of IgG from 7 to 22 mg/dL and those of IgA from 0 to 6 mg/dL; however, IgM is at low, often undetectable levels (Friberg and Tilley-Friberg, 1976). The complete source of these antibodies is not known, although they are found in expressed prostatic fluid (Grayhack et al, 1979) and may be related to infections (Fowler et al, 1982). They are usually found at lower levels in seminal plasma than in blood, but the possibility of diffusion across the "blood-seminal plasma barrier" has not been eliminated (see discussion by Friberg and Tilley-Friberg, 1976).

Expressed prostatic fluid contains considerable amounts of the C3 component of complement, present at 1.82 mg/dL, and this increases nearly 10-fold in fluid collected from patients with prostatic adenocarcinoma to levels of 16.9 mg/dL (Grayhack and Lee, 1981). Prostatitis has also been shown to be related to C3 in men with chronic prostatitis (Blenk and Hofstetter, 1991). Prostatitis and BPH increase the level only approximately twofold. In the same manner, transferrin, an iron-carrying protein, is increased, going from levels of 5.3 mg/dL in normal prostatic fluid to 42.4 mg/dL in prostatic carcinoma (Grayhack and Lee, 1981).

John and colleagues (2003) conducted a prospective study of the ejaculate of 88 patients with chronic prostatitis by surveying IgG, IgA, and IgM and interleukin-1 α , soluble interleukin-2 receptor, and interleukin-6. The control group consisted of 96 normal ejaculates according to the World Health Organization criteria. Ejaculates of patients with chronic prostatitis increased during symptoms and subsided when clinical symptoms decreased. The authors observed that a combination of the humoral immune (IgA and interleukin-6) changes and T-cell-rich infiltrates is suggestive of an autoimmune component of the disease. Alexander and coworkers (2004) studied a group of patients with chronic granulomatous prostatitis consisting of histologically diffuse nonspecific inflammatory changes that include epithelioid histiocytes and occasional multinucleate giant cells admixed with lymphocytes and plasma cells. They have identified an association between the major histocompatibility locus antigen HLA-DRB2*1501 and granulomatous prostatitis and have suggested the possibility that it may be an autoimmune disease.

Zinc α_2 -Glycoprotein

In the seminal plasma, zinc α_2 -glycoprotein (ZAG) is synthesized by PreCs and secreted into seminal fluid (Ding et al, 2007), and it constitutes about 30% of the proteins present in the seminal fluid (Poortmans and Schmid, 1968). The ZAG glycoprotein is found in many body fluids with a molecular mass of 41 kD, and the crystal structure is quite similar to that of a class I major histocompatibility complex (Burgi and Schmid, 1961; Burgi et al, 1989; Sanchez et al,

1999; Delker et al, 2004; Hassan et al, 2008a, 2008b). In addition, ZAG is assigned to the chromosome 7q22.1 based on fluorescent hybridization karyotyping (Hassan et al, 2008a). The crystal structure of ZAG consists of a large groove analogous to class I major histocompatibility complex peptide-binding grooves, and the structure and environment of the groove reflect its role in immunoregulation and in lipid catabolism (Sanchez et al, 1999; Hassan et al, 2008b). ZAG appears naturally in blood, sweat, seminal fluid, breast cyst fluid, cerebrospinal fluid, and urine and is also found in secretory epithelial cells of the liver and the gastrointestinal tract (Tada et al, 1991; Hassan et al, 2008a, 2008b). Biochemically, ZAG stimulates lipid degeneration in adipocytes and appears to be involved in cachexia, a wasting syndrome that can affect people with cancer, acquired immunodeficiency syndrome, and other terminal illnesses (Hirai et al, 1998; Bing et al, 2004; Russell and Tisdale, 2005; Hassan et al, 2008b). The purification and characterization of ZAG from human seminal plasma revealed that it was bound to prolactin-inducible complex (PIP) (Hassan et al, 2008a). With the use of a ZAG tryptic peptide as a standard and a high-flow liquid chromatography–tandem mass spectrometry assay, serum levels in six healthy men were calculated as 3.65 (0.71) mg/L (Bondar et al, 2007). Furthermore, the concentration of ZAG and PIP has been reported to increase dramatically in carcinomas; therefore it has been considered as a good biomarker for prostate, breast, oral, and epidermal carcinomas (Hassan et al, 2008b). Thus ZAG is a protein regulated by glucocorticoids and has the ability to affect fertilization and lipid mobilization (adipokine).

Seminal Vesicle Secretory Proteins

Williams-Ashman (1983) presented a classic review on regulatory features of development and function of the seminal vesicles. The secretory proteins of the seminal vesicles are major proteins and enzymes involved in the rapid clotting of the ejaculate (Cunha et al, 1992). The major clotting protein has been termed *semenogelin* (Lilja and Abrahamsson, 1988). It has been shown to be the seminal vesicle-specific antigen. These clotted proteins from the seminal vesicles serve as substrates for PSA that enzymatically lyse the clot through their protease activity (Lilja, 1985; Aumuller and Seitz, 1990). Beyond the coagulation reaction it is not known what role these seminal vesicle proteins play, but their effects on fertility and uterine sperm motility have been studied in the mouse (Peitz and Olds-Clarke, 1986). Many of the proteins secreted by the seminal vesicles are under androgen regulation (Higgins and Hemingway, 1991; Hagstrom et al, 1992). More recent work (Harvey et al, 1995) has identified an androgen-regulated protease with elastase-like activity within seminal vesicle secretions. The semenogelins I and II are secreted in abundance by the seminal vesicles; and in addition to having coagulum-forming functions and being cleaved by kallikrein-like peptidases to generate biologically active products, the semenogelins are assumed to activate sperm hyaluronidase, affect sperm motility, possess antimicrobial activity, serve as substrates for transglutaminase, and have amyloid properties (Jonsson et al, 2006; de Lamirande, 2007; Hassan et al, 2008b).

In addition, cholesterol and sphingomyelin-rich small, lipid membrane-confined exosome-like vesicles (prostasomes) have been isolated from human semen, and these structures provide an additional source of several hundred proteins that are quite important to fully understanding the biology of reproduction as well as improving our knowledge of the semen coagulation and liquefaction system (Ronquist and Brody, 1985; Arienti et al, 1999; Poliakov et al, 2009). Prostatasomes contain numerous proteins that can affect fertility, promote sperm motility, and stabilize the acrosome reaction (Delves et al, 2007). Sucrose gradient purified prostasomes have been observed by electron microscopy, and their composition has been surveyed after trypsin digestion by liquid chromatography–mass spectrometry (Poliakov et al, 2009). A diversity of structural and functional proteins involved in fertilization, cell adhesion, apoptosis, immunity, metabolism, signal transduction, transport, angiogenesis, and so on have been identified in prostasomes and have opened a new source of urologic scientific investigation to

pursue new biomarkers of disease and elucidate mechanisms of fertility (Delves et al, 2007; Poliakov et al, 2009).

COAGULATION AND LIQUEFACTION OF SEMEN

Within 5 minutes after ejaculation, human semen coagulates into a semisolid gel. On further standing for a 5- to 20-minute period, the clot spontaneously liquefies to form a viscous liquid (Huggins and Neal, 1942; Tauber and Zaneveld, 1976; Mann and Mann, 1981). Calcium-binding substances, such as sodium citrate and heparin, do not inhibit the coagulation process, nor are prothrombin, fibrinogen, or factor XII required because they are absent in seminal plasma (Mann and Mann, 1981). The seminal clot is formed of fibers 0.15 to 10 nm in width, and its morphologic appearance differs from that of a blood fibrin clot (Huggins and Neal, 1942; Tauber and Zaneveld, 1976; Mann and Mann, 1981). Factors affecting blood coagulation do not regulate semen viscosity (Amelar, 1962). From these observations and others, it appears that the coagulation of human semen is different from that of blood.

Examination of split human ejaculates indicates that the first fraction, originating primarily from the Cowper gland and the prostate, contains the liquefaction factors. The final fraction of the ejaculate, enriched in seminal vesicle secretions, is responsible for the coagulation of the ejaculate (Lilja et al, 1987).

It has long been known that prostatic fluid has a dramatic, fibrinolytic-like activity and that 2 mL of this secretion can liquefy 100 mL of clotted blood in 18 hours at 37°C (Huggins and Neal, 1942; Mann and Mann, 1981). The factors involved in such proteolytic activity in semen have been resolved (Huggins and Neal, 1942; Syner et al, 1975; Tauber et al, 1975, 1976; Tauber and Zaneveld, 1976; Mann and Mann, 1981; Zaneveld and Chatterton, 1982; Lilja et al, 1987). Two types of seminal plasma proteolytic enzymes appear to be major factors in the liquefaction process: plasminogen activators and PSA. Two plasminogen activators have been isolated from seminal plasma; they have molecular weights of 70 and 74 kD and appear to be related to urokinase (Propping et al, 1974). It is believed that the plasminogen activators originate from the prostatic secretions.

The seminal plasma contains a variety of other proteolytic enzymes, including pepsinogen, lysozyme, α -amylase, and hyaluronidase. In addition, human semen inhibits the activity of the proteolytic enzyme trypsin, and this is the result of the presence in the seminal plasma of such proteinase inhibitors as α_1 -antitrypsin and α_1 -antichymotrypsin. Coagulation and liquefaction vary in different species. For example, the semen of the bull or dog does not coagulate, whereas rodents, such as the rat and guinea pig, ejaculate a firm pellet that does not appear to liquefy (Tauber et al, 1975, 1976; Tauber and Zaneveld, 1976). In rodents the plugs form through the action of an enzyme called *vesiculase*, which comes from the anterior lobe of the prostate and reacts with seminal vesicle secretions. Because of this action, the anterior lobe of the rodent prostate is also called the *coagulating gland*. Vesiculase is not identical to thrombin because it does not coagulate fibrinogen, nor does thrombin clot the secretions of the seminal vesicles. Williams-Ashman and associates (1977) have established that vesiculase has transamidase activity, catalyzing the formation of γ -glutamyl-lysine cross-links in a clottable protein derived from the seminal vesicles. This seminal vesicle protein, which serves as a substrate for vesiculase, is a basic substance with a molecular weight of 17.9 kD; it has been characterized as to its physical properties.

In summary, it appears that seminal plasma coagulation and liquefaction are under enzymatic control but the biologic purpose of this process has not been resolved. Several key enzymes (e.g., hKLK2 [PSA], hKLK3, hKLK14, PAP) and proteins (e.g., semenogelins, PSP-94, ZAG) of the seminal vesicles and prostate gland are involved in this coagulation and liquefaction system. There have been reports that some infertile men may have impairment of the liquefaction process (Bunge and Sherman, 1954; Bunge, 1970; Eliasson, 1973; Amelar et al, 1977; Jonsson et al, 2006; de Lamirande,

2007; Anahi Franchi et al, 2008; Hassan et al, 2008b; Poliakov et al, 2009).

KEY POINTS: COAGULATION AND LIQUEFACTION OF SEMEN

- PSA is one of several serine proteases secreted by the prostate in high concentrations into the ejaculate. Although its main function may relate to regulation of semen coagulation, it has proved to be a valuable marker of prostate disease states.
- PCI is abundant in the seminal fluid, and it plays a key role in the interaction among semenogelins, PSA, and likely other proteins in semen, resulting in protein-protein interactions critical to semen coagulation and liquefaction.

PROSTATIC SECRETIONS AND DRUG TRANSPORT

Aumuller and Seitz (1990) have reviewed the secretory mechanism for the sex accessory tissues. Isaacs (1983) also reviewed the concepts related to the fluid and drug transport properties of the prostate and seminal vesicles and has compared the composition and volume of prostatic secretion under basal stimulation and under neurologic stimulation during ejaculation or pilocarpine stimulation. Isaacs calculated that under neurologic stimulation there is a 205-fold increase in the total potassium, chloride, and sodium output over the basal secretory rate, and he has shown that the prostate is capable of secreting five times its total content of sodium and chloride during this active secretion. These findings show the tremendous transport powers of this system. Smith and Hagopian (1981) have studied the transepithelial voltage changes during prostatic secretion in the dog and have concluded that although sodium may move passively through the plasma in the prostatic fluid during ejaculation, the movements of potassium and chloride ions involve active transcellular transport. Isaacs and associates (1983) have shown that the androgen-induced secretions can be blocked in the presence of estrogen, although the growth properties and biologic properties of the androgen on the prostate are not markedly altered. This would suggest a direct effect of estrogen in blocking a major transport system in the prostate.

Only a few compounds, including ethanol, iodine, and a few antibiotics, are capable of entering the semen by simple diffusion (Reeves, 1982). Drugs entering prostatic secretions have been of interest because of the prevalence of prostatitis and the need for new modalities of chemotherapy. Earlier, Stamey and colleagues had made extensive studies of the ability of chemotherapeutic agents to concentrate in the prostatic fluid of humans and dogs (Hessl and Stamey, 1971; Stamey et al, 1973), and many other investigators have also contributed to this knowledge (Madsen et al, 1968, 1976, 1978; Fowler et al, 1982). Few drugs reach concentrations in the prostatic secretion that approach or surpass their concentrations in blood, but some exceptions are the basic macrolides erythromycin and oleandomycin, sulfonamides, chloramphenicol, tetracycline, clindamycin, trimethoprim, and fluoroquinolones (Reeves, 1982).

In general, these drugs are assumed to pass across the membrane by nonionic diffusion, possibly by lipid solubility, through the membrane; when they reach the more acidic prostatic fluid they are protonated and acquire a more positive charge. Thus the charged drugs become relatively trapped within the prostatic secretions. Several factors are critical, including the pKa of the drug and the pH of the prostatic secretions, as well as the drug binding to proteins in each compartment. Basic drugs would be more positively charged in acidic prostatic fluid than in blood. Slight changes in pH can have large effects on this nonionic diffusion. Samples of prostatic secretions from humans varied widely in pH from 6 to 8, with a mean value of 6.6; however, with prostatic inflammation the pH tended to be 7 or higher (White, 1975). Although prostatic

secretions are slightly acidic, the pH of freshly ejaculated human semen is slightly alkaline (pH 7.3 to 7.7); on standing, semen first becomes more alkaline with the loss of carbon dioxide and then later acidic owing to accumulation of lactic acid. Drugs may be developed in the future that are transported into the prostate as therapeutic agents, as chemoprotectors, or as a route to the semen to regulate fertility; however, more must be learned about the fundamental transport system in and out of the male reproductive tract before such an approach is feasible.

KEY POINTS: PROSTATIC SECRETIONS AND DRUG TRANSPORT

- Only a few compounds, including ethanol, iodine, and a few antibiotics, are capable of entering the semen by simple diffusion.
- A few exceptions for drugs are the basic macrolides erythromycin and oleandomycin, sulfonamides, chloramphenicol, tetracycline, clindamycin, trimethoprim, and fluoroquinolones. Perhaps these molecules, because of their lipid solubility, are transported by nonionic diffusion.

Natural History of Untreated Benign Prostatic Hyperplasia

Surgery for Benign Prostatic Hyperplasia

Benign prostatic hyperplasia (BPH) is a pathologic process that is one but certainly not the only cause of lower urinary tract symptoms (LUTS) in aging men, also described as “male LUTS.” Despite intense research efforts in the past five decades to elucidate the underlying etiology of prostatic growth in older men, cause-and-effect relationships have not been established. For example, androgens are a necessary but not the only causative aspect of BPH. Previously held notions that the clinical symptoms of male LUTS—in the past erroneously called “prostatism”—are simply due to a mass-related increase in urethral resistance are too simplistic. It is now clear that a significant portion of male LUTS is due to age-related detrusor dysfunction and other conditions such as polyuria, sleep disorders, and a variety of systemic medical conditions unrelated to the prostate-bladder unit.

Historically, voiding symptoms have been related to obstruction of the bladder outlet (Chapple et al, 2008). The traditional association in men is with the prostate, the so-called symptoms of “prostatism.” However, it is well recognized that voiding symptoms poorly correlate with underlying pathophysiology (de la Rosette et al, 1998). Similar symptoms can be produced by any other form of obstruction, such as a urethral stricture or, conversely, by poor function of the lower urinary tract in circumstances in which there is impaired detrusor contractility. This has led to the recognition that, although LUTS may commonly be related to bladder outlet obstruction (BOO) as a result of benign prostatic obstruction, which is often associated with benign prostatic enlargement resulting from the histologic condition of BPH, this is not invariably the case. For example, women also commonly present with voiding symptoms (Irwin et al, 2006). Lepor and Machi (1993) have shown that age-matched community-dwelling men and women have similar levels of symptom frequency and severity. Failure to empty can be related either to an outlet obstruction or to detrusor underactivity of the bladder, or to a combination of both. Postmicturition symptoms, such as postvoid dribbling, occur in both sexes, but most often in men, in whom these symptoms are highly common, are very troublesome, and cause significant interference with quality of life (Reynard et al, 1996). Storage symptoms are currently largely encompassed by the term *overactive bladder syndrome*, which is defined as urgency, frequency, nocturia, and urge incontinence, and which is believed to be correlated with an underlying detrusor overactivity (Abrams et al, 2003). These symptoms tend to be more bothersome than voiding symptoms, especially if they are associated with incontinence. Storage symptoms in both sexes are commonly associated with urinary infections or, more rarely, with other conditions such as bladder stones, carcinoma, or carcinoma in situ in the bladder.

This conception can be shown as partially overlapping populations (Fig. 103-1). While many men over the age of 40 will develop

histologic hyperplasia (i.e., BPH), not all will have bothersome LUTS. Of those who do, some will and others will not develop measurable enlargement of the prostate, which may be referred to as benign prostatic enlargement (BPE). It is common for men to have BPE without having LUTS and vice versa. BOO may also be present with or without LUTS and with or without BPE, and in some cases BOO (i.e., stricture, etc.) exists in men with BPH (Roehrborn, 2008).

Undoubtedly, the constellation of cellular pathologies that give rise to the symptoms of LUTS is far more complex than we currently realize. Only by unraveling these complexities, however, will we be able to design alternative strategies to treat successfully and possibly prevent the adverse impact of BPH on lower urinary tract function.

ETIOLOGY

Histopathologically, BPH is characterized by an increased number of epithelial and stromal cells in the periurethral area of the prostate and thus correctly referred to as *hyperplasia* and not *hypertrophy*, as is often found in the older literature. The observation of new epithelial gland formation is normally seen only in fetal development and gives rise to the concept of embryonic reawakening of the stromal cell's inductive potential (Cunha et al, 1983; Isaacs, 2008). The precise molecular etiology of this hyperplastic process is uncertain. The observed increase in cell number may be due to epithelial and stromal proliferation or to impaired programmed cell death leading to cellular accumulation. Androgens, estrogens, stromal-epithelial interactions, growth factors, and neurotransmitters may play a role, either singly or in combination, in the etiology of the hyperplastic process.

Hyperplasia

In a given organ, the number of cells, and thus the volume of the organ, is dependent upon the equilibrium between cell proliferation and cell death (Isaacs and Coffey, 1989). An organ can enlarge not only by an increase in cell proliferation but also by a decrease in cell death. Although androgens and growth factors stimulate cell proliferation in experimental models, the relative role of cell proliferation in human BPH is questioned because there is no clear evidence of an active proliferative process. Although it is possible that the early phases of BPH are associated with a rapid proliferation of cells, the established disease appears to be maintained in the presence of an equal or reduced rate of cell replication. Increased expression of antiapoptotic pathway genes (e.g., *BCL2*) supports this hypothesis (Kyprianou et al, 1996; Colombel et al,

Figure 103-1. Diagram showing the relationship between histologic hyperplasia of the prostate (BPH), lower urinary tract symptoms (LUTS), benign prostate enlargement (BPE), and bladder outlet obstruction (BOO). The size of the circles does not represent actual proportions but rather illustrates the partial overlap between the different disease definitions. (From Roehrborn CG. Pathology of benign prostatic hyperplasia. *Int J Impot Res* 2008;20[Suppl. 3]:S11–8.)

1998). Androgens not only are required for normal cell proliferation and differentiation in the prostate but also actively inhibit cell death (Isaacs, 1984). In the dog, experimental BPH can be produced by androgens combined with estradiol (Walsh and Wilson, 1976; DeKlerk et al, 1979; Berry et al, 1986b; Juniewicz et al, 1994). Despite a significant increase in gland size, there is actually a reduction in the rate of DNA synthesis compared with untreated controls (Barrack and Berry, 1987), indicating that androgens and estrogens both inhibit the rate of cell death. Neural signaling pathways, especially α -adrenergic pathways, may also play a role in balancing cell death and cell proliferation (Anglin et al, 2002).

The hyperplasia results in a remodeling of the normal prostatic architecture (Untergasser et al, 2005). Epithelial budding from pre-existing ducts and the appearance of mesenchymal nodules characterize the early stages of the process, but the tissue phenotype of patients with established disease is highly variable.

BPH may be viewed as a stem cell disease (Barrack and Berry, 1987). Presumably, dormant stem cells in the normal prostate rarely divide, but when they do, they give rise to a second type of transiently proliferating cell capable of undergoing DNA synthesis and proliferation, thus maintaining the number of cells in the prostate. When the proliferating cells mature through a process of terminal differentiation, they have a finite life span before undergoing programmed cell death. In this paradigm, the aging process induces a block in this maturation process so that the progression to terminally differentiated cells is reduced, reducing the overall rate of cell death. Indirect evidence for this hypothesis comes from the observation that secretion, one parameter of epithelial cell differentiation, decreases with age, suggesting that the number of differentiated cells capable of secretory activity may be decreasing (Isaacs and Coffey, 1989). A survey of human BPH specimens for a marker of cellular senescence (senescence-associated β -galactosidase) demonstrated a higher portion of senescent epithelial cells in men with large prostates, suggesting that an accumulation of those cells may play a role in the development of prostate enlargement (Choi et al, 2000). More recent studies support the hypothesis that impaired cell senescence may play a significant role in the etiology of BPH (Castro et al, 2003).

Hormones may exert their influence over the stem cell population not only with advancing age but also during embryonic and neonatal development (Naslund and Coffey, 1986). The size of the

prostate may be defined by the absolute number of potential stem cells present in the gland, which in turn may be dictated at the time of embryonic development. Studies in animal models have suggested that early imprinting of prostatic tissue by postnatal androgen surges is critical to subsequent hormonally induced prostatic growth. As with the hormonal regulation of adult prostatic tissues, sex steroid hormones may exert their imprinting effect directly or indirectly through a complex series of signaling pathways (Lee and Peehl, 2004).

Role of Androgens

Although androgens do not cause BPH, the development of BPH requires the presence of testicular androgens during prostate development, puberty, and aging (McConnell, 1995; Marcelli and Cunningham, 1999). Patients castrated prior to puberty or who are affected by a variety of genetic diseases that impair androgen action or production do not develop BPH. It is also known that prostatic levels of dihydrotestosterone (DHT) as well as the androgen receptor (AR) remain high with aging despite the fact that peripheral levels of testosterone are decreasing. Moreover, androgen withdrawal leads to partial involution of established BPH (Peters and Walsh, 1987; Isaacs, 2008).

Assuming normal ranges, there is no clear relationship between the concentration of circulating androgens and prostate size in aging men. In the Olmsted County Study of Urinary Symptoms and Health Status among Men cohort (median age 60.9), serum bioavailable testosterone levels were found to decline with increasing age, while the estradiol/bioavailable testosterone ratio increased (Roberts et al, 2004). Bioavailable testosterone correlated negatively and estradiol/bioavailable testosterone ratio correlated positively with prostate volume, but this association was much less apparent after age adjustment. Baseline data from a large BPH medical therapy study confirmed the absence of a relationship between serum testosterone, serum prostate-specific antigen (PSA), and prostate volume (Marberger et al, 2006) (Table 103-1). Conversely, in a 20-year follow-up study, Parsons and colleagues (2010) showed that higher baseline serum DHT levels were associated with an increased risk of BPH. The odds ratios (ORs) for the second, third, and fourth quartiles of DHT were 1.83 (95% confidence interval [CI] 0.96 to 3.47), 1.50 (0.79 to 2.85), and 2.75 (1.46 to 5.19), respectively (P trend = .02). A higher testosterone-to-DHT ratio, however, was associated with a 42% decreased risk of BPH (Parsons et al, 2010; Trifiro et al, 2010).

In the brain, skeletal muscle, and seminiferous epithelium, testosterone directly stimulates androgen-dependent processes. In the prostate, however, the nuclear membrane-bound enzyme steroid 5α -reductase converts the hormone testosterone into DHT, the principal androgen in this tissue (see Fig. 103-1) (McConnell, 1995). Ninety percent of total prostatic androgen is in the form of DHT, principally derived from testicular androgens. Adrenal androgens may constitute 10% of total prostatic androgen, although the importance of this stored hormone source in the etiology of BPH is negligible. Inside the cell, both testosterone and DHT bind to the same high-affinity AR protein (Chatterjee, 2003). DHT is a more potent androgen than testosterone because of its higher affinity for the AR. Moreover, the DHT-receptor complex may be more stable than the testosterone-receptor complex. The hormone receptor then binds to specific DNA binding sites in the nucleus, which results in increased transcription of androgen-dependent genes and ultimately stimulation of protein synthesis (Andriole et al, 2004). Conversely, androgen withdrawal from androgen-sensitive tissue results in a decrease in protein synthesis and tissue involution. Besides inactivation of key androgen-dependent genes (e.g., PSA gene), androgen withdrawal leads to the activation of specific genes involved in programmed cell death (Kyprianou and Isaacs, 1989; Martikainen et al, 1990). Despite the importance of androgens in normal prostatic development and secretory physiology, there is no evidence that either testosterone or DHT serves as the direct mitogen for growth of the prostate in older men. Indeed, neither hormone is mitogenic to cultured prostatic epithelial cells (McKeehan et al,

TABLE 103-1 Absence of Significant Relationship between Serum Testosterone and Serum PSA and Prostate Volume

BASILINE TESTOSTERONE CATEGORY (ng/mL)*	NO. OF INDIVIDUALS (N = 4254)	AGE (yr)	PSA (ng/mL)	PROSTATE VOLUME (mL)	BMI (kg/m ²)	BASILINE SFI SCORE

Modified from Marberger M, Roehrborn CG, Marks LS, et al. Relationship among serum testosterone, sexual function, and response to treatment in men receiving dutasteride for benign prostatic hyperplasia. *J Clin Endocrinol Metab* 2006;91:1323–8.

1984). In the rat ventral prostate, differential gene expression experiments failed to demonstrate direct activation of mitogenic pathways (Wang et al, 1997). However, many growth factors and their receptors are regulated by androgens (see later). Thus the action of testosterone and DHT in the prostate is mediated indirectly through autocrine and paracrine pathways.

Androgen Receptors

The prostate, unlike other androgen-dependent organs, maintains its ability to respond to androgens throughout life. In the penis, AR expression decreases to negligible rates at the completion of puberty (Roehrborn et al, 1987; Takane et al, 1991a, 1991b). Thus, despite high circulating levels of androgen, the adult penis loses its ability for androgen-dependent growth. If the penis maintained high levels of ARs throughout life, presumably the organ would grow until the time of death. In contrast, AR levels in the prostate remain high throughout aging (Barrack et al, 1983; Rennie et al, 1988). In fact, these data suggest that nuclear AR levels may be higher in hyperplastic tissue than in normal control tissues. Age-related increases in estrogen, as well as other factors, may increase AR expression in the aging prostate, leading to further growth (or to a decrease in cell death), despite decreasing levels of androgen in the peripheral circulation and “normal” levels of DHT in the prostate.

The potential role of AR mutations, polymorphisms, or other alterations in the pathogenesis of BPH is unclear (Chatterjee, 2003). A polymorphism in the number of CAG repeats (short versus control) in the AR gene has been associated with larger prostate size and an increased risk of surgery (Giovannucci et al, 1999a, 1999b). However, another study from the Netherlands showed no relationship between the number of CAG repeats and BPH (Bousema et al, 2000). A study of Finnish men found that short CAG repeats were significantly less common in men with BPH compared with control subjects (Mononen et al, 2002). Given the significant variation in reported findings, if short CAG repeats play a role in BPH pathogenesis, it is likely to be minor (Hoke and McWilliams, 2008).

Dihydrotestosterone and Steroid 5 α -Reductase

Intraprostatic DHT concentrations are maintained but not elevated in BPH. Initial studies of resected prostatic tissue suggested that prostatic DHT levels were higher in the hyperplastic gland than in normal control tissues. However, the controls used for these early studies were largely accident victims. Ongoing metabolism of DHT after death lowers the level of this androgen in cadaveric tissues. This was clearly shown in a study by Walsh and colleagues (1983) in which prostatic surgical specimens from men without BPH were used as the control. These investigators demonstrated that DHT

levels are the same in hyperplastic glands as in normal glands. However, the aging prostate maintains a high level of DHT as well as a high level of ARs; thus the mechanism for androgen-dependent cell growth is maintained. There is little question that androgens have at least a permissive role in the development of the disease process.

Two steroid 5 α -reductase enzymes have been discovered, each encoded by a separate gene (Russell and Wilson, 1994). Type 1 5 α -reductase, the predominant enzyme in extraprostatic tissues such as skin and liver, is normally expressed in the 5 α -reductase deficiency syndrome and is inhibited by dutasteride but not substantially by finasteride. Type 2 5 α -reductase is the predominant prostatic 5 α -reductase, although it is also expressed in extraprostatic tissues. Mutations in the type 2 enzyme are responsible for the clinical phenotype observed in the 5 α -reductase deficiency syndrome. It is exquisitely sensitive to inhibition by finasteride and dutasteride (Carson and Rittmaster, 2003). Clearly, the type 2 enzyme is critical to normal development of the prostate and hyperplastic growth later in life. The role of type 1 5 α -reductase in normal and abnormal prostate growth remains to be defined. There is growing evidence to suggest that the type 1 isoenzyme may play a more important role in prostate cancer compared to BPH, as increased levels of mRNA expression, protein, and functional enzymes have been demonstrated in prostate cancer (Thomas et al, 2008). Given that finasteride produces prostate size reduction identical to that with dual type 1/type 2 inhibitors and roughly equivalent to that with castration, it is unlikely that type 1–derived DHT is critical to hyperplastic growth.

Immunohistochemical studies with type 2 5 α -reductase-specific antibodies show primarily stromal cell localization of the enzyme (Thigpen et al, 1993; Silver et al, 1994). Epithelial cells uniformly lack type 2 protein, and some basal epithelial cells stain positively. Type 1 5 α -reductase protein could not be detected in BPH or prostate cancer using initially available antibodies, although trace levels of type 1 mRNA have been seen in normal prostates, BPH, and cancer (Shirakawa et al, 2004). A study with a selective type 1 antibody demonstrated positive staining in only 7% of BPH cases (Thomas et al, 2003). In the same study, type 1 enzymatic activity was found in only 2 of 29 BPH specimens.

These data demonstrate that the stromal cell plays a central role in androgen-dependent prostatic growth and that the type 2 5 α -reductase enzyme within the stromal cell is the key androgenic amplification step. Thus a paracrine model for androgen action in the gland (Fig. 103-2) is evident. In addition, it is possible that circulating DHT produced in the skin and liver may act on prostate epithelial cells in a true endocrine fashion (McConnell, 1995). If dual type 1/type 2 5 α -reductase inhibition has clinical utility over selective type 2 inhibitors, it is likely to be due to inhibition of peripherally produced DHT.

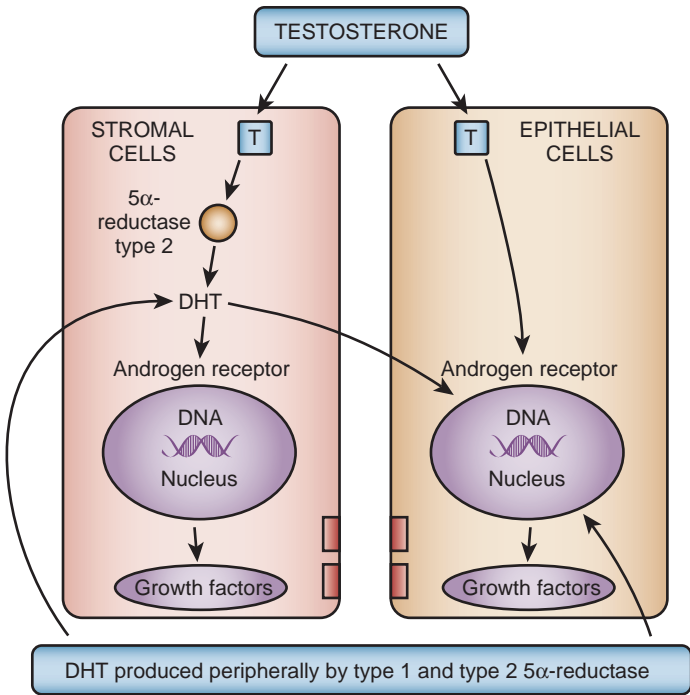

Figure 103-2. Testosterone (T) diffuses into the prostate epithelial and stromal cell. T can interact directly with the androgen (steroid) receptors bound to the promoter region of androgen-regulated genes. In the stromal cell, a majority of T is converted into dihydrotestosterone (DHT)—a much more potent androgen—which can act in an autocrine fashion in the stromal cell or in a paracrine fashion by diffusing into epithelial cells in close proximity. DHT produced peripherally, primarily in the skin and liver, can diffuse into the prostate from the circulation and act in a true endocrine fashion. In some cases the basal cell in the prostate may serve as a DHT production site, similar to the stromal cell. Autocrine and paracrine growth factors may also be involved in androgen-dependent processes within the prostate. (From Roehrborn CG. Pathology of benign prostatic hyperplasia. *Int J Impot Res* 2008;20[Suppl. 3]:S11–8.)

Immunohistochemical studies in open enucleated BPH specimens show considerable intra- and interprostatic 5 α -reductase, making studies of its distribution based on single or one-time biopsy material very difficult (Sherwood et al, 2003).

Polymorphisms in the type 2 steroid 5 α -reductase enzyme (SRD5A2) have been reported, but their linkage to BPH is uncertain. The SRD5A2 gene on chromosome 2p23 frequently encompasses A49T and V89L substitutions and a TA dinucleotide repeat polymorphism. The 89L allele has been associated with lower enzyme activity, whereas the 49T allele has been associated with higher activity. Longer TA repeats are associated with mRNA instability and thus decreased enzyme activity. The number of L alleles, but not testosterone alleles or TA repeats, in one study correlated significantly with the presence of BPH (Salam et al, 2005). In the Olmsted County Study population, consistent associations between SRD5A2 genotypes and BPH were not demonstrated, although there was a weak correlation between V89L polymorphisms and prostate volume (Roberts et al, 2005).

Androgen withdrawal may partially exert its effect on the prostate through vascular effects (Buttayan et al, 2000). Castration induces acute and drastic vasoconstriction of blood vessels in the rat prostate (Hayek et al, 1999). This effect does not appear to be mediated through vascular endothelial growth factor (VEGF) (Burchardt et al, 2000). There is indirect evidence to suggest that abnormalities in the prostatic vascular system produced by other disease states (e.g., diabetes) may be a risk factor for BPH (Parsons et al, 2006; Parsons, 2007).

TABLE 103-2 Comparison of ER- α and ER- β Expression and Activities in the Prostate Gland

	ER- α	ER- β
Localization	Stromal	Epithelial

ER, estrogen receptor.
From Prins GS, Korach KS. The role of estrogens and estrogen receptors in normal prostate growth and disease. *Steroids* 2008;73:233–44.

Role of Estrogens

There is animal model evidence to suggest that estrogens play a role in the pathogenesis of BPH; the role of estrogens in the development of human BPH, however, is less clear. In the dog, where estrogens act synergistically with androgens to produce experimental BPH, estrogen appears to be involved in induction of the AR (Moore et al, 1979). Estrogen may, in fact, “sensitize” the aging dog prostate to the effects of androgen (Barrack and Berry, 1987). The canine prostate contains an abundance of high-affinity estrogen receptors (ERs). In the dog, estrogen treatment stimulates the stroma, causing an increase in the total amount of collagen (Berry et al, 1986a, 1986b). There are at least two forms of the ER: Estrogen receptor α (ER- α) is expressed by prostate stromal cells, and estrogen receptor β (ER- β) is expressed by prostate epithelial cells (Prins et al, 1998). The estrogenic response of the prostate is determined by the type of ER present within the prostatic cells. Experiments in knockout mice suggest a “constraining influence” of estrogens on the prostate (Krege et al, 1998). In vitro studies suggest that upregulation of ER- α in cultured prostate stromal cells is also associated with upregulation of fibroblast growth factor (FGF)-2, FGF-7, and other growth factors; the addition of androgens down-regulated the ER and various stroma-derived growth factors (Smith et al, 2000, 2002).

Different actions may be mediated by the stromal ER- α and epithelial ER- β (Prins and Korach, 2008). Evidence also indicates that estrogen action mediated through the separate receptors may contribute to the etiology and progression of multiple prostate disease states (Table 103-2). These findings provide new avenues and alternative approaches for the treatment of prostate diseases, including prostate cancer, with novel therapies directed at ERs or estrogen metabolism. Since the two types of ER may play distinct and perhaps opposing roles in many diseases of the prostate, including cancer progression, it is possible that receptor-specific agonists and antagonists may prove beneficial in therapeutic strategies in future clinical trials. A recent randomized, placebo-controlled study using an ER- β agonist in men with male LUTS failed, however, to show any effect on symptoms, serum PSA, prostate size, and urodynamic parameters (manuscript submitted).

Serum estrogen levels increase in men with age, absolutely or relative to testosterone levels. There is also suggestive evidence that

intraprostatic levels of estrogen are increased in men with BPH. Patients with larger volumes of BPH tend to have higher levels of estradiol in the peripheral circulation (Partin et al, 1991). In the Olmsted County Study cohort, in men with above-median levels of bioavailable testosterone, the serum estradiol level correlated positively with prostate volume, even after adjusting for age (Roberts et al, 2004). Data on obesity, serum testosterone, estradiol, and prostate volume are conflicting (Zucchetto et al, 2005). Although there are relatively low concentrations of classic high-affinity ERs in human BPH (Farnsworth, 1996; Sciarra and Toscano, 2000), there may be a sufficient amount for biologic activity.

From experimental studies with aromatase inhibitors, it appears that decreases in intraprostatic estrogen in animal models may lead to reduction in drug-induced stromal hyperplasia (Farnsworth, 1996, 1999). At present, however, the role of estrogens in human BPH is not as firmly established as the role of androgens. Species variation and cause-and-effect relationships are problematic.

There are high levels of progesterone receptor in the normal and hyperplastic prostate. However, the role of the progesterone receptor in normal prostatic physiology as well as in BPH remains to be defined.

Regulation of Programmed Cell Death

Programmed cell death (apoptosis) is a physiologic mechanism crucial to the maintenance of normal glandular homeostasis (Kerr and Searle, 1973). Cellular condensation and fragmentation precede phagocytosis and degradation, during which the apoptotic cell is phagocytosed by neighboring cells and degraded by lysosomal enzymes. Apoptosis occurs without activation of the immune system but requires both RNA and protein synthesis (Lee, 1981). In the rat prostate, active cell death occurs naturally in the proximal segment of the prostatic ductal system in the presence of normal concentrations of plasma testosterone (Lee et al, 1990). Androgens (presumably testosterone and DHT) appear to suppress programmed cell death elsewhere in the gland. Following castration, active cell death is increased in the luminal epithelial population as well as in the distal region of each duct. Tenniswood (1986) suggested that there is regional control over androgen action and epithelial response, with androgens providing a modulating influence over the local production of growth regulatory factors that varies in different parts of the gland. Members of the transforming growth factor- β (TGF- β) family are likely candidates for this regulatory step (Martikainen et al, 1990).

In the rat prostate, at least 25 different genes are induced following castration (Montpetit et al, 1986). Normal glandular homeostasis requires a balance between growth inhibitors and mitogens, which respectively restrain or induce cell proliferation but also prevent or modulate cell death. Abnormal hyperplastic growth patterns, such as BPH, might be induced by local growth factor or growth factor receptor abnormalities, leading to increased proliferation or decreased levels of programmed cell death.

Stromal-Epithelial Interaction

There is abundant experimental evidence to demonstrate that prostatic stromal and epithelial cells maintain a sophisticated paracrine type of communication. The growth of canine prostate epithelium can be regulated by cellular interaction with the basement membrane and stromal cells. Isaacs and Coffey (1989), using a marker of canine prostatic epithelial cell function, demonstrated that epithelial cells grown on plastic quickly change their behavior. The cells begin to grow rapidly and change their cytoskeletal staining pattern. In contrast, if the cells are grown on prostatic collagen, they maintain their normal secretory capacity and cytoskeletal staining pattern and do not grow rapidly. This is strong evidence that one class of stromal cell excretory protein (i.e., extracellular matrix [ECM]) partially regulates epithelial cell differentiation. Thus BPH may be due to a defect in a stromal component that normally inhibits cell proliferation, resulting in loss of a normal "braking" mechanism for proliferation. This abnormality could

act in an autocrine fashion to lead to proliferation of stromal cells as well.

Further evidence of the importance of stromal-epithelial interactions in the prostate comes from the elegant developmental studies of Cunha and colleagues, which demonstrate the importance of embryonic prostatic mesenchyme in dictating differentiation of the urogenital sinus epithelium (Cunha et al, 1980, 1983, 2003; Cunha and Donjacour, 1987; Cunha, 1994, 1996). The process of new gland formation in the hyperplastic prostate suggests a "reawakening" of embryonic processes in which the underlying prostatic stroma induces epithelial cell development (McNeal, 1990). Many of the prostatic stromal-epithelial interactions observed during normal development and in BPH may be mediated by soluble growth factors or by the ECM, which itself has growth factor-like properties. This model is even more intriguing, given the cellular localization of 5 α -reductase (and thus DHT production) in the prostatic stromal cell (Silver et al, 1994).

The complexity of the stromal-ECM-epithelial relationship is revealed in studies of the ECM signaling protein CYR61. CYR61 is an ECM-associated protein that promotes adhesion, migration, and proliferation of epithelial and stromal cells. A variety of growth factors increase the expression of CYR61 (an early immediate response gene) in both cell types, and the suppression of CYR61 expression by an antisense oligonucleotide significantly affects normal cell morphology (Sakamoto et al, 2003, 2004a, 2004b). CYR61 expression is significantly increased in human BPH tissues and is induced by lysophosphatidic acid (an endogenous lipid growth factor).

As our understanding of stromal-epithelial cell relationships in the prostate increases, it is possible that therapies may be designed to induce regression of established BPH by modulating these autocrine/paracrine mechanisms.

Growth Factors

Growth factors are small peptide molecules that stimulate, or in some cases inhibit, cell division and differentiation processes (Steiner, 1995; Lee and Peehl, 2004). Cells that respond to growth factors have on their surface receptors specific for that growth factor that in turn are linked to a variety of transmembrane and intracellular signaling mechanisms. Interactions between growth factors and steroid hormones may alter the balance of cell proliferation versus cell death to produce BPH (Fig. 103-3). Lawson's group was the first to demonstrate that extracts of BPH stimulate cellular growth. This putative prostatic growth factor was subsequently found on sequence analysis to be basic fibroblastic growth factor (bFGF) (Story et al, 1989). Subsequently, a variety of growth factors

Figure 103-3. Prostate hyperplasia is probably due to an imbalance between cell proliferation and cell death. Androgens play a necessary but probably permissive role. Growth factors are more likely to be sites of primary defects. DHT, dihydrotestosterone; EGF, epidermal growth factor; IGFs, insulin-like growth factors; KGF, keratinocyte growth factor; TGF- β , transforming growth factor- β .

have been characterized in normal, hyperplastic, and neoplastic prostatic tissue. In addition to bFGF (FGF-2), acidic FGF (FGF-1), Int-2 (FGF-3), keratinocyte growth factor (KGF [FGF-7]), TGF- β , and epidermal growth factor (EGF) have been implicated in prostate growth. TGF- β is a potent inhibitor of proliferation in normal epithelial cells in a variety of tissues. In models of prostatic cancer, there is evidence that malignant cells have escaped the growth inhibitory effect of TGF- β (McKeehan and Adams, 1988). Similar mechanisms may be operational in BPH (Salm et al, 2000), leading to the accumulation of epithelial cells (Kundu et al, 2000). Growth factors may also be important in modulating the phenotype of the prostate smooth muscle cell (Peehl and Sellers, 1998).

There is mounting evidence of interdependence between growth factors, growth factor receptors, and the steroid hormone milieu of the prostate (Rennie et al, 1988; Lee and Peehl, 2004). Although data on the absolute level of growth factor and growth factor receptors in hyperplastic as opposed to normal tissue are conflicting, it is likely that growth factors play some role in the pathogenesis of BPH. However, further research is necessary to establish the role of growth factors in a disease process in which cellular proliferation is not obvious.

If cellular proliferation is a component of the BPH process, it appears that growth stimulatory factors such as the FGF-1, -2, -7, and -17 families, VEGF, and insulin-like growth factor (IGF) may play a role, with DHT augmenting or modulating the growth factor effects. In contrast, TGF- β , which is known to inhibit epithelial cell proliferation, may normally exert a restraining influence over epithelial proliferation that is lost or downregulated in BPH (Wilding et al, 1989; Sporn and Roberts, 1990, 1991; Peehl et al, 1995; Cohen et al, 2000; Lee and Peehl, 2004). TGF- β 1 is a potent mitogen for fibroblasts and other mesenchymal cells but is also an important inhibitor of epithelial cell proliferation (Roberts and Sporn, 1993). TGF- β 1 also regulates ECM synthesis and degradation and can induce cells to undergo apoptosis. In addition, TGF- β upregulates the production of bFGF, which is known to be an autocrine growth factor for prostate stromal cells (Story et al, 1993), and at least on one prostate smooth muscle cell line (PSMC1), TGF functions as an autocrine mitogen (Salm et al, 2000). Thus upregulation of TGF- β 1 (which is expressed in prostate stromal cells) during BPH would favor expansion of the stromal compartment.

Indirect evidence to support this view comes from studies of reconstituted mouse prostate (Yang et al, 1997). Interestingly, the observation that TGF- β 1 may regulate smooth muscle contractile protein expression suggests that TGF- β isoforms may be physiologic regulators of prostatic smooth muscle function (Orlandi et al, 1994). Cohen and colleagues (2000) found that stromal cells isolated from BPH specimens exhibited a blunted TGF- β growth inhibition relative to normal stromal cells and that the blunted response appeared to be due to a reduction in TGF-mediated increase in IGF binding protein 3 (IGFBP-3) expression. TGF- β may stimulate the overexpression of versican (chondroitin sulfate proteoglycan 2) in the ECM through inhibition of key metalloproteases (ADAMTS lineage) that normally degrade versican, leading to accumulation in the ECM (Cross et al, 2006). An increased risk for BPH was described in patients with a codon 10 polymorphism in TGF- β (Li et al, 2004).

The first evidence of increased FGF-2 levels in BPH came from the studies of Begun and coworkers (1995), who demonstrated a two- to threefold elevation of FGF-2 in BPH compared with histologically normal glands. Further studies have demonstrated that both FGF-2 and FGF-7 are overexpressed in BPH tissues (Ropiquet et al, 1999). The major target of FGF-2 is thought to be the stroma itself (autocrine), although transgenic mice overexpressing FGF-2 develop glandular epithelial hyperplasia (Konno-Takahashi et al, 2004). KGF, a member of the FGF family (FGF-7), is produced in prostatic stromal cells (Yan et al, 1992). However, cell surface receptors for stroma-derived KGF are expressed exclusively in epithelial cells. As a result, FGF-7 (or a homolog) is the leading candidate for the factor mediating the stromal cell-based hormonal regulation of the prostatic epithelium. There is direct evidence that

FGF-7 plays this role in the androgen-dependent mesenchymal-epithelial interactions involved in development of the seminal vesicle (Alarid et al, 1994). Abnormalities in stromal FGF-7 production or epithelial FGF-7 receptor could promote epithelial cell proliferation. Indirect evidence supporting this hypothesis comes from a study of transgenic mice overexpressing FGF-7 that develop atypical prostatic hyperplasia (Kitsberg and Leder, 1996). McKeehan's laboratory demonstrated that FGF-10, a homolog of FGF-7, is expressed at high levels in the rat prostate, specifically in stromal cells of smooth muscle origin (Lu et al, 1999; Nakano et al, 1999). FGF-10 expression is increased by androgens and may have a mitogenic effect on prostate epithelium. Other studies suggest that cells expressing FGF-7 are localized in the stroma immediately adjacent to the epithelium, suggesting that the epithelial cells may induce FGF-7 expression. The paracrine factor most likely responsible for this effect is the cytokine interleukin (IL)-1 α (Giri and Ittmann, 2000; Lee and Peehl, 2004).

Some investigators have speculated that local hypoxia in the prostate (perhaps from atherosclerosis or other vascular events) is the initial event that induces FGF production (Lee and Peehl, 2004). Further growth of BPH nodules could impede blood flow, leading to further hypoxia (Parsons and Kashefi, 2008; Parsons et al, 2008). Hypoxia leads to upregulation of hypoxia-inducible factor-1, which in turn increases the secretion of FGF-2 and FGF-7 from stromal cells.

Other growth factors implicated in BPH include FGF-17 (Polnaszek et al, 2004), FGF-10, and VEGF (Walsh et al, 2002). It remains difficult to ascertain which of the growth factors and growth factor receptors are key mediators of the BPH disease process and which are bystanders.

A unique animal model provides additional evidence that FGF-like factors may be involved in the etiology of BPH. A transgenic mouse line expressing the Int-2/FGF-3 growth factor demonstrated androgen-sensitive epithelial hyperplasia in the male mouse prostate that was histologically similar to human and canine BPH (Tutrone et al, 1993).

IGFs, binding proteins, and receptors also appear to be important modulators of prostatic growth, at least as it relates to cell growth in culture (Peehl et al, 1995; Lee and Peehl, 2004). A transgenic mouse model with overexpression of IGF-1 demonstrated prostate gland enlargement (Konno-Takahashi et al, 2003). Studies of BPH tissue demonstrate a higher concentration of IGF-2 in the periurethral area than in the peripheral zone (Monti et al, 2001). A study of Chinese men demonstrated a significant correlation between circulating IGF-1 and IGFBP-3 levels and BPH (Dahle et al, 2002), but a study of the Olmsted County Study cohort data failed to demonstrate any relationship between serum IGF-1 and prostate volume (Roberts et al, 2003).

Other Signaling Pathways

Sympathetic signaling pathways are important in the pathophysiology of LUTS, as is evident from the use of drugs interfering with the adrenergic nervous system, such as α -adrenergic receptor blockers, which are highly effective for the treatment of LUTS (American Urological Association Practice Guidelines Committee, 2003). In addition, there is increasing evidence that sympathetic pathways may be important in the pathogenesis of the hyperplastic growth process (McVary et al, 1994, 2005). α -Blockade, in some model systems, can induce apoptosis (Anglin et al, 2002). α -Adrenergic pathways can also modulate the smooth muscle cell phenotype in the prostate (Lin et al, 2000). All the components of the renin-angiotensin system (RAS) are present in prostatic tissue and may be activated in BPH (Dinh et al, 2001, 2002; Fabiani et al, 2001). Either with or without sympathetic modulation, local RAS pathways may contribute to cell proliferation and smooth muscle contraction.

The early growth response 1 gene (*EGR1*) transcription regulation pathway was found to be active in a BPH cell line (Mora et al, 2005). Also of interest is the finding that α_2 -macroglobulin, a large protein that binds PSA and many growth factors, is very highly

expressed in human prostate and is upregulated in BPH (Lin et al, 2005). Trapping and inactivation of inhibitory molecules could promote growth pathways.

Potential Role of Inflammatory Pathways and Cytokines in Benign Prostatic Hyperplasia

An additional source of growth factors in human BPH tissue may be the inflammatory cell infiltrates seen in many men with BPH. In the 1990s, descriptive studies suggested a link between inflammation and BPH-related growth. Theyer and associates (1992) reported extensive infiltration of human BPH tissues by activated T cells. Peripheral blood and tumor-infiltrating T cells are known to express VEGF, a potent epithelial mitogen (Blotnik et al, 1994; Freeman et al, 1995). T cells are known to produce and secrete a variety of other growth factors, including heparin-binding EGF-like growth factor and bFGF/FGF-2. Thus T cells present in the local prostate environment were thought to be capable of secreting potent epithelial and stromal mitogens that promote stromal and glandular hyperplasia.

In the last 5 years, specific inflammatory mediator pathways have been studied in detail to elucidate the potential role of these pathways in BPH pathogenesis (Fig. 103-4). A large number of cytokines

and their receptors are seen in BPH tissue (Konig et al, 2004). Specifically, significant levels of interleukins IL-2, IL-4, IL-7, and IL-17, interferon- γ (IFN- γ), and their relevant receptors are found in BPH tissue (Kramer et al, 2002; Steiner et al, 2003a, 2003b). IL-2, IL-7, and IFN- γ stimulate the proliferation of prostatic stromal cells in vitro. Prostatic epithelial cell senescence results in increased expression of IL-8, which can promote proliferation of nonsenescent epithelial and stromal cells (Castro et al, 2004). Macrophage inhibitory cytokine 1 is expressed in normal prostate tissue but significantly downregulated in BPH (Kakehi et al, 2004; Taoka et al, 2004). Chronic inflammation in BPH is also associated with focal upregulation of cyclooxygenase-2 in the glandular epithelium (Wang et al, 2004). To date, however, no firm cause-and-effect relationships have been established between prostatic inflammation and related cytokine pathways and stromal-epithelial hyperplasia.

Recent work from an Italian laboratory suggests that the metabolic syndrome may be a clinical determinant of a higher risk for prostatic inflammation and thus for male LUTS and BPH, and that AR activation by testosterone (in a rabbit model) and DHT may have a protective effect upon prostatic inflammation (Vignozzi et al, 2012a, 2012b; Gacci et al, 2013). This work, if confirmed, effectively establishes a link between the role of androgenic steroids and prostatic inflammation in the pathophysiology of male LUTS and BPH.

Figure 103-4. A, Tissue effect of T cell-derived proinflammatory cytokines on the pathogenesis and progression of immune inflammation and stromal growth in the aging prostate (T cells indicated in red). B, Role of smooth muscle cells (indicated in red) in maintenance and propagation of immune infiltration in the aging prostate. DC, dendritic cell; HSD, hydroxysteroid dehydrogenase; IL, interleukin; PSA, prostate-specific antigen; PAP, prostatic acid phosphatase; TGF- β , transforming growth factor- β ; TLR, toll-like receptor. (From Kramer G, Mitteregger D, Marberger M. Is benign prostatic hyperplasia [BPH] an immune inflammatory disease? *Eur Urol* 2007;51:1202–16.)

A review of BPH as a potentially autoimmune disease was published by [Kramer and coworkers \(2007\)](#). [Figure 103-4](#) illustrates the immunologic key features of chronic inflammation in BPH and the present interpretation of these changes in the development and progression of BPH. A summary of clinical observations regarding the role of inflammation in clinical BPH and suggesting it as a therapeutic target was published recently ([Gandaglia et al, 2013](#)).

Genetic and Familial Factors

There is substantial evidence that **BPH has an inheritable genetic component**. Sanda and colleagues conducted a retrospective case-control analysis of surgically treated BPH patients and control subjects at Johns Hopkins ([Partin et al, 1994](#); [Sanda et al, 1994](#)). The BPH patients were men whose resected prostate weights were in the highest quartile (>37 g) and whose age at prostatectomy was in the lowest quartile. The **hazard/function ratio for surgically treated BPH among first-degree male relatives of the BPH cases compared with the first-degree male relatives of the controls was 4.2 (95% CI, 1.7 to 10.2), demonstrating a very strong relationship (Table 103-3)**. The results did not appear to be due to differences in health-seeking behavior between the two groups. A segregation analysis showed that the results were most consistent with an **autosomal dominant inheritance pattern**. Utilizing this model, approximately 50% of cases of men undergoing prostatectomy for BPH at less than 60 years of age could be attributable to an inheritable form of the disease. In contrast, only about 9% of men undergoing prostatectomy for BPH at more than 60 years of age would be predicted to have a familial risk. In addition, monozygotic twins demonstrate a higher concordance rate of BPH than dizygotic twins ([Partin et al, 1994](#)).

In a community-based cohort study of more than 2000 men, Roberts and colleagues found an elevated risk of moderate to severe urologic symptoms in men with a family history of an enlarged prostate and a family history of BPH compared with those with no history ([Roberts et al, 1995](#)). Analysis of the subjects who participated in the U.S. finasteride clinical trial identified 69 men who had three or more family members with BPH, including the proband ([Sanda et al, 1997](#)). Regression analysis demonstrated that **familial BPH was characterized by large prostate size, with a mean prostate volume of 82.7 mL in men with hereditary BPH compared with 55.5 mL in men with sporadic BPH (Sanda et al, 1995)**. Serum androgen levels and the response to 5 α -reductase inhibition were similar in familial and sporadic BPH. A more recent familial aggregation study in the finasteride database confirmed that a strong family history of early onset and large prostate volume is more likely to be associated with inheritance of risk than symptom severity or other factors ([Pearson et al, 2003](#)).

These studies clearly demonstrate the presence of a familial form of BPH and suggest the presence of a gene contributing to

the pathogenesis of the disease. The studies of [Meikle and coworkers \(1997, 1999\)](#) also support a genetic basis for BPH. Preliminary studies demonstrate evidence of DNA mutations ([White et al, 1990](#)), DNA hypomethylation ([Bedford and van Helden, 1987](#)), abnormalities of nuclear matrix protein expression ([Partin et al, 1993](#)), miscellaneous genetic polymorphisms ([Werely et al, 1996](#); [Konishi et al, 1997](#); [Habuchi et al, 2000](#)), and abnormal expression of the Wilms tumor gene (*WT1*) ([Dong et al, 1997](#)) in human BPH. By analyzing 14 single nucleotide polymorphisms associated with prostate cancer, genetic variants in 2q31 and 5p15 were found to be associated with aggressive BPH in a Chinese population ([Qi et al, 2013](#)). However, the specific gene or genes involved in familial BPH or that contribute to the risk of significant prostatic enlargement in sporadic disease remain to be elucidated.

Other Etiologic Factors

Androgens and soluble growth factors are clearly not the only important factors for the development of BPH. All mammalian prostates studied have testosterone, DHT, and ARs as well as most of the known growth factor signaling pathways; however, only dog and man develop BPH. Interestingly, another glandular organ that remains androgen responsive throughout life, the seminal vesicle, does not develop hyperplasia. Obviously, other mechanisms or cofactors must be present in these two unique species making them susceptible to the disease. Nonandrogenic substances from the testis, perhaps transmitted through the vas deferens or deferential blood vessels, for example, may play some role ([Dalton et al, 1990](#)). Rats with intact testes treated with exogenous androgen demonstrate a greater degree of prostatic growth than castrated rats treated with androgen. [Sutkowski and coworkers \(1993\)](#) have demonstrated that human spermatocele fluid is mitogenic to both human prostatic epithelial and stromal cells in culture. Similar results have been seen in castrated versus testes-intact dogs treated with exogenous androgen and exogenous testosterone and estradiol combination ([Juniewicz et al, 1994](#)). In addition to increases in prostate weight, the incidence of histologic BPH was significantly higher in the dogs with intact testes. [Grayhack and colleagues \(1998\)](#) have identified a putative substance that may be a candidate for such a factor.

Prolactin has long been speculated to play a role in BPH because of the known effects of this hormone on prostate cells in vitro. Transgenic mice overexpressing the prolactin gene develop significant enlargement of the prostate ([Wennbo et al, 1997](#)). However, despite the documented presence of prolactin receptors in the human prostate and low circulating levels of the hormone, the role of prolactin in human prostate disease is unclear. In a mice knockout model, prolactin-mediated hyperplastic prostate growth involved epithelial-stromal interaction through epithelial prolactin/prolactin receptor signals. The stromal fibromuscular AR could

modulate such epithelial-stromal interacting signals, such that by targeting the stromal AR with a degradation enhancer, a reduction of prostate size was observed, an observation that might be used in future therapy (Lai et al, 2013).

Molecular profiling, fingerprinting, microarrays, and high-throughput screening tools have uncovered new genes, as well as known genes not previously associated with BPH. Preliminary findings from the Getzenberg laboratory (Prakash et al, 2002; Sakamoto et al, 2004b; Shah et al, 2004; Minnery and Getzenberg, 2005) and other groups (Fromont et al, 2004; Dhanasekaran et al, 2005) suggest that new markers for BPH and new therapeutic targets will be forthcoming in the next few years.

PATHOPHYSIOLOGY

The pathophysiology of BPH is complex (Fig. 103-5). Prostatic hyperplasia increases urethral resistance, resulting in compensatory changes in bladder function. However, the elevated detrusor pressure required to maintain urinary flow in the presence of increased outflow resistance occurs at the expense of normal bladder storage function. Obstruction-induced changes in detrusor function, compounded by age-related changes in both bladder and nervous system function, lead to urinary frequency, urgency, and nocturia, the most bothersome BPH-related complaints. Thus an understanding of BPH pathophysiology requires detailed insight into obstruction-induced bladder dysfunction.

Pathology

Anatomic Features

McNeal (1978) demonstrated that BPH first develops in the periurethral transition zone of the prostate (Fig. 103-6). The transition zone consists of two separate glands immediately external to the preprostatic sphincter. The main ducts of the transition zone arise on the lateral aspects of the urethral wall at the point of urethral angulation near the verumontanum. Proximal to the origin of the

transition zone ducts are the glands of the periurethral zone that are confined within the preprostatic sphincter and course parallel to the axis of the urethra. All BPH nodules develop either in the transition zone or in the periurethral region (McNeal, 1978, 1990). Although early transition zone nodules appear to occur either within or immediately adjacent to the preprostatic sphincter, as the disease progresses and the number of small nodules increases, they can be found in almost any portion of the transition or periurethral zone. However, the transition zone also enlarges with age, unrelated to the development of nodules.

One of the unique features of the human prostate is the presence of the prostatic capsule, which plays an important role in the development of LUTS (Caine and Schuger, 1987). In the dog, the only other species known to develop naturally occurring BPH, symptoms of BOO and urinary symptoms rarely develop because the canine prostate lacks a capsule. Presumably the capsule transmits the "pressure" of tissue expansion to the urethra and leads to an increase in urethral resistance. Thus the clinical symptoms of BPH in man may be due not only to age-related increases in prostatic size but also to the unique anatomic structure of the human gland. Clinical evidence of the importance of the capsule can be found in series that clearly document that incision of the prostatic capsule (transurethral incision of the prostate) results

Figure 103-6. Zonal anatomy of the prostate as first described by McNeal (1978). Sagittal (A) and coronal (B) sections of the prostate showing the peripheral zone, transition zone, central zone, verumontanum, and proximal urethral segment, as well as the preprostatic sphincter and ejaculatory duct. Figure 103-5. The pathophysiology of benign prostatic hyperplasia (BPH) involves complex interactions between urethral obstruction, detrusor function and dysfunction, and urine production.

Figure 103-7. Diagrams of hyperplastic prostatic tissue obstructing the prostatic urethra, forming “lobes.” A, Isolated middle lobe enlargement. B, Isolated lateral lobe enlargement. C, Lateral and middle lobe enlargement. D, Posterior commissural hyperplasia (median bar). (After Randall [1931], from Roehrborn CG. Pathology of benign prostatic hyperplasia. *Int J Impot Res* 2008;20[Suppl. 3]:S11–8.)

in a significant improvement in outflow obstruction, despite the fact that the volume of the prostate remains the same.

The size of the prostate does not correlate with the degree of obstruction. Thus other factors such as dynamic urethral resistance, the prostatic capsule, and anatomic pleomorphism are more important in the production of clinical symptoms than the absolute size of the gland. In some cases, predominant growth of periurethral nodules at the bladder neck gives rise to the “middle lobe” (Fig. 103-7). The middle lobe must be of periurethral origin because there is no transition zone tissue in this area. It is not clear whether middle lobe growth occurs at random in men with BPH or whether there is an underlying genetic susceptibility to this pattern of enlargement.

Histologic Features

BPH is a hyperplastic and not a hypertrophic process; that is, there is a net increase in the number of cells and not in the size of the cells. Histologic studies document an increase in the cell number (McNeal, 1990). In addition, thymidine uptake studies in the dog clearly indicate an increase in DNA synthesis in experimentally induced BPH (Barrack and Berry, 1987). The term *benign prostatic hypertrophy* is pathologically incorrect.

McNeal’s studies demonstrate that the majority of **early periurethral nodules are purely stromal in character** (McNeal, 1990). These small stromal nodules resemble embryonic mesenchyme with an abundance of pale ground substance and minimal collagen. It is unclear whether these early stromal nodules contain mainly fibroblast-like cells or whether differentiation toward a smooth muscle cell type is occurring. In contrast, **the earliest transition zone nodules represent proliferation of glandular tissue** that may be associated with an actual reduction in the relative amount of

Figure 103-8. Stromoglandular hyperplasia of the prostate showing glandular (upper left) and stromal (lower right) tissue (hematoxylin and eosin stain). (From Roehrborn CG. Pathology of benign prostatic hyperplasia. *Int J Impot Res* 2008;20[Suppl. 3]:S11–8.)

stroma. The minimal stroma seen initially consists primarily of mature smooth muscle, not unlike that of the uninvolved transition zone tissue. These **glandular nodules are apparently derived from newly formed small duct branches** that bud off from existing ducts, leading to a totally new ductal system within the nodule. This type of **new gland formation is quite rare** outside embryonic development. This proliferative process leads to a tight packing of glands within a given area as well as an increase in the height of the lining epithelium. There appears to be hypertrophy of individual epithelial cells as well. Again, the observed increase in transition zone volume (TZV) with age appears to be related not only to an increased number of nodules but also to an increase in the overall size of the zone.

During the first 20 years of BPH development, the disease may be predominantly characterized by an increased number of nodules, and the subsequent growth of each new nodule is generally slow. Then a second phase of evolution occurs in which there is a significant increase in large nodules. In the first phase, the glandular nodules tend to be larger than the stromal nodules. In the second phase, when the size of individual nodules is increasing, the size of glandular nodules clearly predominates.

There is significant pleomorphism in stromal/epithelial ratios in resected tissue specimens. Studies from primarily **small resected glands demonstrate a predominance of fibromuscular stroma** (Shapiro et al, 1992). Larger glands, predominantly those removed by enucleation, demonstrate primarily epithelial nodules (Franks, 1976) (Fig. 103-8). However, an increase in stromal/epithelial ratios does not necessarily indicate that this is a “stromal disease”; stromal proliferation may well be due to “epithelial disease.”

Importance of Prostatic Smooth Muscle

Regardless of the exact proportion of epithelial to stromal cells in the hyperplastic prostate, there is no question that **prostatic smooth muscle represents a significant volume of the gland** (Shapiro et al, 1992) (Fig. 103-9). Although the smooth muscle cells in the prostate have not been extensively characterized, presumably their contractile properties are similar to those seen in other smooth muscle organs. The spatial arrangement of smooth muscle cells in the prostate is not optimal for force generation; however, there is no question that **both passive and active forces in prostatic tissue play a major role in the pathophysiology of BPH**. The factors that determine passive tone in the prostate remain to be elucidated. The series elastic elements in the stromal and epithelial cells and (most important) the ECM contribute to passive tissue force, independent of active smooth muscle contraction. However, **stimulation of the adrenergic nervous system clearly**

Figure 103-9. Prostate sections obtained from men with symptomatic benign prostatic hyperplasia were analyzed by double immunoenzymatic staining and quantitative image analysis. The percent area density of smooth muscle and connective tissue is significantly greater than glandular epithelium and glandular lumen area density (mean \pm SEM). (From Shapiro E, Becich MJ, Hartanto V, et al. The relative proportion of stromal and epithelial hyperplasia is related to the development of symptomatic benign prostate hyperplasia. *J Urol* 1992;147:1293–7.)

results in a dynamic increase in prostatic urethral resistance. Blockade of this stimulation by α -receptor blockers clearly diminishes this response. However, α -blockade does not decrease passive tension in the prostate, which may be an equal determinant of urethral resistance.

Several additional observations on the prostatic stromal/smooth muscle cell are important. It is generally assumed that the stromal cells are resistant to the effects of androgen withdrawal. In short-term studies, androgen ablation appears to affect primarily the epithelial cell population. In general, however, stromal cells have much slower turnover rates than epithelial cells. If the effect of androgen ablation is primarily to increase cell death rates, a decrease in stromal cell numbers may not be appreciated until a year or more of therapy. Thus further study is required to determine whether the stromal cell is really resistant to androgen withdrawal. Likewise, it cannot be assumed that hormonal therapy has no effect on the stroma even if stromal cell volumes are not decreased. In a variety of smooth muscle cell systems (e.g., vascular and myometrial), contractile proteins, neuroreceptors, and ECM proteins are regulated by a variety of hormones and growth factors. In vitro, androgens have been shown to modulate the effects of α agonists on prostate smooth muscle cells (Smith et al, 2000). Thus a given therapy may affect stromal cell function without decreasing the absolute number or volume of cells.

Studies of human tissue samples by Lin and colleagues (2000) have clearly shown that the smooth muscle cells from men with BPH have a significant downregulation of smooth muscle myosin heavy chain and a significant upregulation of nonmuscle myosin heavy chain. This myosin expression pattern is typical of de-differentiated smooth muscle and indicates either proliferation or loss of normal modulation pathways.

Active smooth muscle tone in the human prostate is regulated by the adrenergic nervous system (Roehrborn and Schwinn, 2004). The α_1 -adrenoreceptor nomenclature has been standardized (Hieble et al, 1995) to reconcile differences in nomenclature based on pharmacologic and molecular studies. Receptor binding studies clearly demonstrate that α_{1A} is the most abundant adrenoreceptor subtype present in the human prostate (Lepor et al, 1993a, 1993b; Price et al, 1993). Moreover, the α_{1A} receptor clearly mediates active tension in human prostatic smooth muscle. It is still unclear whether other factors may regulate smooth muscle contraction. Endothelin and endothelin receptors (Kobayashi et al, 1994a, 1994b; Imajo et al, 1997; Walden et al, 1998) have been reported

in human prostate. However, the physiologic role of this potent contractile agent in prostate smooth muscle function remains to be defined. Various components of the kallikrein-kinin system (e.g., bradykinin) may play a role in the regulation of both smooth muscle proliferation and contraction in the prostate (Walden et al, 1999; Srinivasan et al, 2004).

The presence of type 4 and type 5 phosphodiesterase isoenzymes in the prostate and the detrusor muscle of the bladder implies that phosphodiesterase inhibitors may be appropriate candidate therapies for BPH-related LUTS (Uckert et al, 2001, 2008, 2009). In fact, placebo-controlled trials have verified a beneficial effect of commercially available drugs for the treatment of erectile dysfunction (ED) in men with LUTS and BPH (McVary et al, 2007; Roehrborn et al, 2008; Stief et al, 2008).

The role of adrenergic stimulation in the prostate may exceed simple smooth muscle contraction. Adrenergic neurotransmitters are known to regulate expression of contractile protein genes in cardiac myocytes (Kariya et al, 1993) and to be involved in the development of cardiac hypertrophy (Matsui et al, 1994). Interestingly, evidence suggests that testosterone may regulate the expression of adrenergic receptors, at least in the kidney (Gong et al, 1995). It is possible that adrenergic neurotransmitters may play a role in prostatic smooth muscle cell regulation as well as contraction (Smith et al, 2000). α -Adrenergic blockade in patients with documented BPH leads to a significant downregulation of normal contractile protein gene expression, specifically smooth muscle myosin heavy chain.

Autonomic nervous system overactivity may contribute to LUTS in men with BPH. McVary and coworkers (2005) demonstrated that autonomic nervous system activity, as measured by a standard set of physiologic tests, plasma, and urinary catecholamines, correlates positively with symptom score and other BPH measures. Serum norepinephrine increase after tilt predicted prostate size (transition zone).

The Bladder's Response to Obstruction

Current evidence suggests that the bladder's response to obstruction is largely an adaptive one. However, it is also clear that many lower tract symptoms in men with BPH or prostate enlargement are related to obstruction-induced changes in bladder function rather than to outflow obstruction directly. Approximately one third of men continue to have significant voiding dysfunction and mostly storage symptoms after surgical relief of obstruction (Abrams et al, 1979). Obstruction-induced changes in the bladder are of two basic types. First, the changes that lead to *detrusor instability* or decreased compliance are clinically associated with symptoms of frequency and urgency. Second, the changes associated with decreased *detrusor contractility* are associated with further deterioration in the force of the urinary stream, hesitancy, intermittency, increased residual urine, and (in a minority of cases) detrusor failure. Acute urinary retention (AUR) should not be viewed as an inevitable result of this process. Many patients presenting with AUR have more than adequate detrusor function, with evidence of a precipitating event leading to the obstruction.

Much of our knowledge of the detrusor's response to obstruction is based on experimental animal studies. Limited information is available on the natural history of the human bladder's response to obstruction. Gosling and colleagues have demonstrated that the major endoscopic detrusor change, trabeculation, is due to an increase in detrusor collagen (Gosling and Dixon, 1980; Gosling et al, 1986). Severe trabeculation is associated with significant residual urine (Barry et al, 1993), suggesting that incomplete emptying may be due to increased collagen rather than impaired muscle function. Severe trabeculation, however, is seen in fairly advanced disease. In experimental animal models, the initial response of the detrusor to obstruction is the development of smooth muscle hypertrophy (Levin et al, 1995, 2000). It is likely that this increase in muscle mass, although an adaptive response to increased intravesical pressure and maintained flow, is associated with significant intra- and extracellular changes in the smooth muscle

cell that lead to detrusor instability and in some cases impaired contractility. Obstruction also induces changes in smooth muscle cell contractile protein expression, impaired energy production (mitochondrial dysfunction), calcium signaling abnormalities, and impaired cell-cell communication (Levin et al, 1995, 2000).

There is considerable evidence that the response of the detrusor smooth muscle cell to stress (increased load related to outlet obstruction) is not as adaptive as the response of skeletal muscle to stress. In the latter case, a relatively normal repertoire of contractile protein genes are upregulated and an increased number of normally organized contractile units assemble in the muscle cell. In the detrusor smooth muscle cell, load-induced hypertrophy leads to a change in myosin heavy chain isoform expression (Lin and McConnell, 1994; Cher et al, 1996) and to a significant alteration in the expression of a variety of thin filament-associated proteins (Mannikarottu et al, 2005a, 2005b, 2006). Taken together, these observations strongly suggest that smooth muscle cells revert to a secretory phenotype in response to obstruction-induced hypertrophy. One consequence of this phenotypic switch is increased ECM production. The detrusor smooth muscle cell is a key contributor to the complex of symptoms associated with prostatic obstruction. Additional research in this area is required (Christ and Liebert, 2005).

In experimental animal models, unrelieved obstruction is associated with the development of significant increases in detrusor ECM (collagen) (Levin et al, 1995, 2000). This also appears to be the case in the human, although cause-and-effect relationships have not been established (Gosling et al, 1986). In addition to obstruction-induced changes in the smooth muscle cells and ECM of the bladder, there is increasing evidence that obstruction may modulate neural-detrusor responses as well (Steers et al, 1990, 1999; Clemow et al, 1998, 2000). Altered neural control of micturition has been noted in aging rats, including reduced bladder contractility, impaired central processing, and altered sensation (Chai et al, 2000).

Independent of obstruction, aging produces some of the same changes in bladder function, histology, and cellular function (Nordling, 2002). There is suggestive evidence from animal models that atherosclerosis and the resultant chronic bladder ischemia or hypoxia induced by other mechanisms (e.g., increased bladder wall tension) may contribute to bladder pathology (Tarcan et al, 1998; Azadzi et al, 1999, 2003, 2008; Azadzi, 2003).

EPIDEMIOLOGY

Definitions

The study of epidemiology determines the distribution and determinants of diseases in humans. From this evolve the components of descriptive epidemiology, which is the description of disease incidence, mortality, and prevalence by person, place, and time, and analytical epidemiology, which is the search for determinants of disease risk that may serve to increase prospects for prevention (Oishi et al, 1998). Epidemiologists assess and compare rates of diseases within one population stratified by sex, age, and other demographic and socioeconomic parameters, and between populations of different culture, ethnicity, lifestyle, and diet.

The following definitions of rates are important to understand:

- **Incidence:** number of diseased people per 100,000 population per year
- **Prevalence:** number of existing cases per 100,000 population at a distinct target date
- **Mortality:** number of deaths per 100,000 population per year
- **Fatality:** number of deaths per number of diseased

Although for highly fatal conditions (i.e., those with a high fatality and mortality rate) the incidence rate (i.e., the rate of people developing the condition in a year) is of preeminent interest, for conditions such as BPH, which are rather benign in their course, the prevalence rate (i.e., the number of men having the condition at a given point in time) is of greater interest.

There is no globally accepted epidemiologic definition of BPH; thus prevalence and incidence rates must be viewed in the context

KEY POINTS: ETIOLOGY AND PATHOPHYSIOLOGY

- The development of BPH requires an intact androgen signaling pathway, but androgens do not cause the disease.
- In the absence of obvious cellular proliferation, the hyperplastic process must be due to an imbalance between cell death and cell proliferation, leading to cell accumulation in both the epithelial and stromal compartments.
- BPH is said to be a “stromal disease,” but it remains unclear whether the initiating events occur in the stromal compartment, the epithelial compartment, or both.
- BPH stroma is a complex mixture of smooth muscle cells and ECM. Much of a given patient’s urethral resistance is due to the passive elastic properties of the prostate tissue that cannot be “relaxed” with α -adrenergic blockade.
- Paracrine and autocrine growth factors seem to be the primary factors that stimulate or inhibit stromal and epithelial growth.
- Inflammation, common in BPH specimens, may play a role in the pathogenesis of the disease through cytokines that promote cell growth or lead to smooth muscle contraction.
- BPH can have a familial inheritance, especially if large prostate volumes and surgical intervention as a young age are seen in the pedigree.
- The bladder’s response to obstruction is only partially adaptive. Smooth muscle cells subjected to increased load undergo hypertrophy, but the phenotype of the cell changes, ECM production is increased, contractile protein expression is altered, and cell-to-cell signaling is impaired.
- Aging, perhaps through vascular mechanisms, leads to further alteration in bladder biology that in all likelihood amplifies the effects of obstruction. Prostate growth is only one component of LUTS in aging men. Physicians tend to overlook the significant contribution of aging, bladder dysfunction, nervous system changes, and systemic disease that in many cases has more impact on symptoms than the size of the prostate.

of the definitions chosen by the investigator reporting the data (Barry, 1990a, 1990b). The prevalence of BPH thus can be calculated based on histologic criteria (autopsy prevalence) or on clinical criteria (clinical prevalence). Since the clinical definitions vary widely, it is easier to compare the autopsy or histologic prevalence of BPH. Despite the low mortality and fatality rates for BPH in modern series, a review of these data is interesting and revealing from a historical point of view.

Lastly, descriptive epidemiologic studies can be divided into cross-sectional (a population stratified by baseline parameters is assessed one single time to determine if and how certain measures change depending on the parameter of interest) and longitudinal (a population is assessed at baseline and at regular intervals to study the changes in parameters of interest stratified by age or other demographic criteria). Considering the cost and logistical difficulties involved with longitudinal follow-up of a cohort over time, it is obviously easier to perform cross-sectional studies. The majority of studies addressing LUTS and clinical BPH are cross-sectional in nature and are discussed below. Furthermore, there are by definition no longitudinal autopsy studies of any condition, and histologically based longitudinal studies are exceedingly difficult to carry out because of the need for repetitive tissue procurement.

Descriptive Epidemiologic Studies

Histologic or Autopsy Prevalence

The definition of BPH is the presence of stromoglandular hyperplasia in a surgical specimen or, in the case of autopsy series, in whole

Figure 103-10. Age-stratified autopsy prevalence of histologic benign prostatic hyperplasia from different series and (smoothed) average. (From Berry SJ, Coffey DS, Walsh PC, et al. The development of human benign prostatic hyperplasia with age. *J Urol* 1984;132:474-9.)

prostates removed after death from men not dying from prostate conditions. The 1984 landmark study by Berry and colleagues summarized the data from five studies demonstrating that no men under the age of 30 had evidence of BPH, and that the prevalence rose with each age group, peaking at 88% in men in their 80s. Figure 103-10 demonstrates the age-stratified prevalence based on several rigorously performed autopsy studies in the United States, England, Austria, Norway, Denmark, China, Japan, and India. The prevalence increases rapidly in the fourth decade of life, reaching nearly 100% in the ninth decade. It is striking that the age-specific autopsy prevalence is remarkably similar in all populations studied regardless of ethnic and geographic origin (Moore, 1943; Swyer, 1944; Franks, 1954; Karube, 1961; Harbitz and Haugen, 1972; Haugen and Harbitz, 1972; Pradhan and Chandra, 1975; Holund, 1980; Berry et al, 1984; Carter and Coffey, 1990).

Cross-sectional Studies of Clinical Prevalence

Descriptive epidemiology relies on the presence of a single universally accepted definition of *disease*. The definitions of BPH, however, have undergone several changes in the past decade, and at present no single criterion can be applied. In the past the term *prostatism* was used, incorrectly referring to the prostate as the sole source of the typical LUTS found in aging men. Tage Hald pointed out that there are at least three inter-related phenomena that can be assessed independently, namely the symptoms (formerly called “prostatism”), enlargement of the prostate gland, and presence of obstruction (Nielsen et al, 1994). In a given patient, all three, two of the three, or only one of the three entities might be present. Paul Abrams coined the term *lower urinary tract symptoms* to replace the old and inappropriate term *prostatism* (Chapple et al, 2008). When evaluating elderly men, one can therefore stratify them by the level of LUTS into mildly, moderately, and severely symptomatic according to a standardized symptom severity and frequency questionnaire (Barry et al, 1992a). The same patients then can be further classified based on the degree of prostatic enlargement as measured by digital rectal examination (DRE), transrectal ultrasonography (TRUS), or magnetic resonance imaging (MRI), and lastly by the presence and degree of BOO as measured by flow rate recordings or invasive pressure-flow studies. The diagram in Figure 103-1 attempts to illustrate the difficulties in using different disease definitions. Of all men over the age of 40, a certain proportion will develop histologic hyperplasia of the prostate (i.e., “BPH”). Of those, some but not all will develop LUTS, while others may have

LUTS as a result of reasons other than BPH (e.g., overactive bladder or other bladder- and detrusor-related conditions, urethral stricture, stones, inflammation). Prostate enlargement occurs in some but again not all men with histologic BPH and LUTS, and some men with enlarged glands may not have any symptoms at all. Lastly, urodynamically proven obstruction may be present in men who have either one, several, or all of histologic BPH, LUTS, and enlarged glands, whereas others may have obstruction without having any evidence of BPH (e.g., urethral stricture, prostate cancer, primary bladder neck sclerosis). In addition to the mere enumeration of symptoms by frequency of occurrence, the bother associated with the symptoms, interference with activities of daily living, and the impact the symptoms have on quality of life are important distinguishing characteristics.

Accordingly, when studying the prevalence of *clinical BPH*—admittedly an imprecise term for the above-described constellation of LUTS, bother, interference, and quality-of-life impact, with or without enlargement, obstruction, and so on—disease definitions may be applied that take either one or several of these items into consideration. For the subsequent discussion, it is important to recognize that very few if any clear cutoff points have been established that allow differentiation between whether a disease is absent or present (e.g., one might argue that a prostate volume over 30 mL constitutes “clinical BPH,” but others might argue for a higher or lower cutoff point; similar observations may be made for symptoms, degrees of obstruction, etc.). Thus rather than describing the true prevalence of a “disease” in populations, one can describe the distribution of certain attributes of that disease in different populations stratified by age. Figure 103-11 illustrates the different estimates of prevalence of “disease” when different definitions are applied, ranging from autopsy prevalence to a combination of clinical threshold parameters and insurance examination data (Berry et al, 1984; Garraway et al, 1991; Chute et al, 1993; Gu et al, 1994; Jolleys et al, 1994; Bosch et al, 1995a; Guess, 1995; Moon et al, 1995; Overland et al, 2001).

Symptom Severity and Frequency

From a pragmatic point of view, studies of symptom severity and frequency are of greatest importance in a disease that is rarely fatal and is characterized by its effect on the quality of life. The development, validation, and translation with cultural and linguistic validation of the standardized, self-administered seven-item American Urological Association Symptom Index (AUASI, also known as the International Prostate Symptom Score [IPSS]) has been a pivotal event in the clinical research on LUTS and BPH (Barry et al, 1992a, 1992b; O’Leary et al, 1992). With the total score running from 0 to 35 points, patients scoring 0 to 7 points are classified as mildly symptomatic, those scoring from 8 to 19 points as moderately symptomatic, and those scoring 20 to 35 points as severely symptomatic. The instrument is an integral part of virtually every epidemiologic study as well as treatment studies in the field, and the availability of validated translations in many common languages allows cross-cultural comparisons of unprecedented scope. Socioeconomic factors do not seem to influence responses to the questionnaire (Moon et al, 1994), and fundamentally similar responses are obtained when the questionnaire is self-administered, read to the patient, mailed in, or administered in some other way (Barry et al, 1995a), or readministered in a scrambled format (Barnboym et al, 1999). However, there is no question, that subtle differences in comprehension of the translated questionnaire, as well as different perception of the symptoms, willingness to admit to the symptoms, acceptance of symptoms as a natural sign of aging, and other factors are at least partially the cause of cross-cultural differences in symptom severity reported in the literature.

Figure 103-12 shows the prevalence of at least moderate to severe symptoms stratified by decade of life as reported in 11 cross-sectional population-based studies from around the world (Garraway et al, 1991; Chute et al, 1993; Hunter et al, 1994; Norman et al, 1994; Bosch et al, 1995a; Moon et al, 1995; Tsukamoto et al, 1995; Hunter et al, 1996; Sagnier et al, 1996; Homma et al, 1997;

Figure 103-11. Prevalence of disease using autopsy series, clinical diagnosis, low maximum flow rate, palpable prostatic enlargement by digital rectal examination (DRE), and community-based studies. BLSA, Baltimore Longitudinal Study of Aging; IPSS, International Prostate Symptom Score; Qmax, peak flow rate; Sx, Symptom; TRUS, transrectal ultrasonography. (Data from Berry et al, 1984; Garraway et al, 1991; Chute et al, 1993; Gu et al, 1994; Jolleys et al, 1994; Bosch et al, 1995a; Moon et al, 1995; Homma et al, 1997; Chicarro-Molero et al, 1998; Overland et al, 2001.)

Overland et al, 2001). A very large international investigation of LUTS in Asian men was undertaken by Homma and colleagues (1997), in which 7588 men from Japan, China, Taiwan, Korea, the Philippines, Thailand, Singapore, Pakistan, India, and Australia were queried. The finding of 18%, 29%, 40%, and 56% of men in their 40s, 50s, 60s, and 70s, respectively, having moderate to severe symptoms is in line with the other studies reported both from Asia and from Europe and North America. In addition to the major community-based studies listed, other studies have been published with similar findings, but often done under less stringent conditions (Nacey et al, 1995; Tay et al, 1996). Despite the significantly different proportion of men admitting to moderate to severe symptoms, a clear trend toward an increase in symptom scores with advancing age is noticeable in all reported studies.

Bother, Interference, and Health-Related Quality of Life

Bother and interference with activities of daily living due to LUTS are equally if not more important than the enumeration of symptom frequency and severity alone (Garraway et al, 1993b; Roberts et al, 1994b). Embarrassment resulting from symptoms has been found to be an important determinant in seeking medical care (Roberts et al, 1994b). LUTS and clinical BPH only marginally affect overall quality of life as measured, for example, with the Medical Outcomes Study 36-item short form health survey (Hunter et al, 1995). Accordingly, several instruments were developed and validated to assess bother, interference, and the disease-specific quality of life and sexual function (Epstein et al, 1992; Barry et al, 1995b; Hansen et al, 1995; Lukacs et al, 1995; O'Leary et al, 1995; Donovan et al, 1996).

These instruments have not been as widely applied to cross-sectional descriptive epidemiologic studies as compared to the IPSS score. However, as observed for symptom severity and frequency, both bother and interference scores increase with advancing age, and disease-specific health-related quality of life (HRQOL) measures are significantly worse in men with higher symptom frequency and severity ratings in population-based studies done in Olmsted County in the United States, in Forth Valley in Scotland, in France, and in a small fishing village in Japan (Shimamaki-mura) (Girman et al, 1998).

Prostate Size

Prostate size can be estimated by DRE, although the reliability across observers is in general considered poor (Roehrborn et al, 1997). An analysis of the Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial verified the significant errors associated with the DRE-assessed prostate size (Pinsky et al, 2006). In addition, DRE tends to underestimate true prostate size as determined by TRUS or other imaging modalities. The magnitude of the underestimation increases with increasing prostate size from 25% up to 50% or more (Roehrborn et al, 1997). For the purpose of epidemiologic studies, TRUS and MRI measurements are preferred, although MRI measurements are somewhat expensive when attempting cross-sectional examinations of populations. TRUS volume measurements using the prolate ellipsoid volume formula are the most widely accepted measure of prostate volume, with reasonable statistical performance characteristics particularly when performed by a single or several well-trained examiners (Sech et al, 2001).

Figure 103-12. Prevalence of at least moderate to severe symptoms stratified by decade of life as reported in cross-sectional population-based studies from around the world. IPSS, International Prostate Symptom Score. (Data from Garraway et al, 1991; Chute et al, 1993; Hunter et al, 1994, 1996; Norman et al, 1994; Bosch et al, 1995a; Moon et al, 1995; Tsukamoto et al, 1995; Sagnier et al, 1996; Homma et al, 1997; Overland et al, 2001; Gray et al, 2004.)

Three-dimensional TRUS appears to provide even more accurate measurements, although such technology is not available in urologists' offices for the most part (Giubilei et al, 2005).

In general, in all cross-sectional studies prostate volume as assessed by TRUS has been found to increase slowly but steadily with advancing age. The slight differences in the absolute volume measures, and the different slopes of increase with advancing age, may be caused by differences in the population examined as follows (Fig. 103-13).

A cohort of 344 men between 40 and 60 years old with no evidence of BPH who were enrolled in an alopecia study had baseline endorectal coil MRI measurements done (Roehrborn et al, 2000a). Mean total prostate volume (TPV) increased from 31.3 to 33.7, 36.1, and 43.1 mL in increments of 5 years. MRI tends to yield prostate volume measurements approximately 10% larger compared to TRUS. A series of 100 men ages 40 to 80 years without BPH or LUTS underwent TRUS measurements of TPV and TZV. TPV increased from 22.1, 29.1, and 41.5 to 43.2 mL, and TZV from 7.2 to 9.9, 19.0, and 19.6 mL, by decade (Benaim et al, 1998). A cross-sectional study of 611 Norwegian men from 55 to 70 years of age exhibited increases in TPV from 26.5 to 31.0 to 32.0 mL in increments of 5 years (Overland et al, 2001), and Jakobsen examined patients between 30 and 50 years by TRUS, the mean TPV being 23.9 and 25.7 mL per decade of life (Jakobsen et al, 1988). TPV and TZV were assessed in 1104 men above the age of 40 years in a Spanish cross-sectional study, yielding increases from 23.4 to 41.9 mL for TPV and from 7.9 to 21.9 mL for TZV (Chicharro-Molero et al, 1998). Finally, the baseline data from the Olmsted County Study provided data on men from 40 to 79 years of age (Oesterling et al, 1993).

Overall, TPV increases in these cross-sectional studies from approximately 25 mL for men in their 30s to 35 to 45 mL for men in their 70s, while TZV increases from 15 to 25 mL for similarly aged men. The similarities between the TPV and TZV

Figure 103-13. Mean estimates for total prostate volume (TPV) and transitional zone volume (TZV) based on one autopsy series (Berry et al, 1984), one series of baseline MRI measurements in men with alopecia (Roehrborn et al, 2000b), and cross-sectional population-based studies (Torp-Pedersen et al, 1988; Oesterling et al, 1993; Bosch et al, 1994; Benaim et al, 1998; Chicharro-Molero et al, 1998; Overland et al, 2001).

measurements done in the different studies are striking particularly when considering the different measurement methods used (see Fig. 103-13).

Measures of Obstruction

Subvesical obstruction can only be measured by invasive pressure-flow studies, while nonintubated free flow rates provide at best an indirect measure for the probability of obstruction being present (Abrams, 1995). Unfortunately, no large-scale cross-sectional studies have been done employing pressure-flow studies because of the invasive and costly nature of the test, and it is unlikely that significant data sets will ever become available.

It is commonly accepted that a maximum flow rate of less than 10 mL/sec indicates a high probability of obstruction, while a flow rate of greater than 15 mL/sec indicates a low probability, with the 10- to 15-mL/sec range presenting an intermediate range. The utility of this categorization is reduced by several observations. First, the maximum flow rate is somewhat dependent of the voided volume (Girman et al, 1993). This has prompted some to propose a nomogram to correct for this phenomenon; however, at present no single nomogram is accepted universally (von Garrelts, 1956, 1957, 1958; Scott and McIlhane, 1961; Beck and Gaudin, 1969; Susset et al, 1973; Siroky et al, 1979, 1980; Drach and Steinbronn, 1986; Haylen et al, 1989). A high degree of diurnal variability (Golomb et al, 1992) and within-subject day-to-day variability (Barry et al, 1995c) further reduces the utility of flow rate recording in defining disease.

Aging men and women experience a decrease in the maximum urinary flow rate that is nearly linear in nature. In the Olmsted County Study, the median flow rate decreased from 20.3 mL/sec for men 40 to 44 years old to 11.3 mL/sec for men 75 to 79 years old (Girman et al, 1993), and similar declines have been reported from other cross-sectional studies. When applying combined thresholds such as at least moderate symptoms (>7 points) on the IPSS score and a maximum flow rate of less than 15 mL/sec, in the Olmsted County Study 17% of men in their 50s, 27% of men in their 60s, and 35% of men in their 70s would fall into such a category (Jacobsen et al, 1995b), versus 14.4%, 28.6%, and 38.7% of men in the respective age groups in a Spanish population-based study (Chicharro-Molero et al, 1998).

Analytical Epidemiologic Studies

Analytical epidemiologic studies address the search for determinants of a disease. Inasmuch as a clear disease definition is lacking, such a search could attempt to find determinants for LUTS, prostate growth, and/or BOO, consistent with the previously outlined concepts. The presence of functioning testes at the time of puberty (hormonal factor) as a required permissive element has long been established and accepted (McConnell, 1991), and age has been shown to be the most critical determinant of all aspects of this complex entity. Numerous other demographic and environmental factors have been suggested as risk factors or contributors to the disease process. When evaluating the associations identified, one has to critically ask whether or not other factors could contribute to the association without there being a cause-and-effect relationship. For example, it seems intuitive that the husbands and family members of nurses are more likely to seek medical care and practice preventive medicine. Therefore the detection rates of prostate cancer in a cohort of nurses' husbands might be higher not due to a truly higher incidence rate of cancer, but due to an increased rate of seeking medical attention and an increase in the number of diagnosed cases of cancer. Such pitfalls are abundant in epidemiologic studies and have to be suspected and carefully ruled out.

Religion

The case-control study by Morrison (1978), the cohort study by Lytton and colleagues (1968), and the Normative Aging Study (Glynn et al, 1985) all revealed Jewish religion to be associated with

a higher prostatectomy rate (2.2- to 2.6-fold increase). However, the fact that Jewish religion is not associated with an increase in the diagnosis of BPH allows the speculation that Jewish patients are more likely to see a physician or to be offered surgical therapy.

Socioeconomic Factors

Araki and associates (1983) found higher rates of BPH in higher income groups, while in contrast Glynn and colleagues (1985) reported higher rates of surgery in lower income groups. One might argue that higher income groups might have better access to health care, while lower income groups might submit more readily to the suggestion of a surgical procedure. Education and socioeconomic status do not influence responses to the IPSS (Moon et al, 1994; Badia et al, 2001), but they do appear to influence both expectations from treatment for BPH and perception of improvement, with patients in higher income strata requiring a larger drop in symptom scores following treatment to perceive subjectively similar levels of improvement (Padley et al, 1997). This finding suggests at least some impact of socioeconomic factors not in the growth of the prostate or measures of obstruction, but rather in the perception of symptoms. Data from the Olmsted County Study suggest a relationship between care-seeking behavior and physician visit and retirement status. Bivariate analysis suggested significant associations between a propensity to seek care for physical reasons and retirement (OR 2.0, 95% CI 1.1 to 2.6), age of 65 years or more (OR 1.9, 95% CI 1.5 to 2.4), incomplete high school education (OR 1.6, 95% CI 1.1 to 2.2), and an annual income of less than \$25,000 (OR 1.4, 95% CI 1.1 to 1.9). Multivariable logistic regression analysis demonstrated that retired men were more likely to have a high propensity to seek care (OR 1.7, 95% CI 1.2 to 2.4), with the other variables no longer being significant (Roberts et al, 1997a).

Our understanding of the impact of some socioeconomic factors on LUTS and BPH has deepened with the help of two studies, the European Prospective Investigation into Cancer and Nutrition and the Epidemiology of LUTS (EpiLUTS) studies and the Boston Area Community Health (BACH) survey (Rosen et al, 2008; Kaplan et al, 2009) (Table 103-4). It is likely that the longitudinally designed BACH survey, with a balanced enrollment of men and women stratified by age and race/ethnicity, will in the future contribute significantly to our understanding of LUTS in both men and women. A symptom-based cluster analysis was performed in both cohorts and remarkably similar clusters of symptoms were identified, allowing for an in-depth analysis of their association with comorbidities and other factors (Rosen et al, 2008). In the BACH survey, decreasing household income and increasing difficulties in paying for health care were associated with increasingly more severe symptom clusters (Hall et al, 2009).

Sexual Activity and Vasectomy

Ekman (1989) suggested that the increase in the fibromuscular stroma is a result of sexual activity, and many authors since then have attempted to find relevant associations. Morrison (1992) reported a 49% reduction in risk for prostatectomy in widowed versus single men; a similar association could not be verified by other authors. Cross-sectional data from the Olmsted County Study suggest that the frequency of ejaculation has no effect on LUTS, peak urinary flow rates, or prostate volume; the apparent protective association appears to be an artifact caused by the confounding effects of age (Jacobsen et al, 2003). The decrease in sexual ability and frequency of sexual activity with advancing age, exactly when the prevalence of BPH increases, in fact might suggest a reverse relationship, namely a causative effect of BPH on sexual function (Altwein and Keuler, 1992).

Recent evidence suggests a strong correlation between the severity of LUTS and impairment of sexual function, that is, ED as well as ejaculatory disturbances (Boyle et al, 2003; Chung et al, 2003; Rosen et al, 2003). Cross-sectional questionnaire-based data from various countries suggest that ED and ejaculatory disturbances increase with advancing age but also within each decade of life

TABLE 103-4 Overview of the EpiLUTS Study and BACH Survey

EPI LUTS	BACH
DESCRIPTION Cross-sectional, population-representative, Internet-based survey conducted in the United States, the United Kingdom, and Sweden in 30,000 (U.S., 20,000; U.K., 7500; Sweden, 2500) men and women ages 40–99 years (mean age, 56.6 years)	Population-based epidemiologic survey among 5503 randomly selected adults residing in Boston, ages 30–79 years, in three race/ethnic groups (2301 men, 3202 women; 1767 black, 1877 Hispanic, 1859 white respondents)
LUTS PREVALENCE 1 LUTS at least sometimes: 72.3% (men), 76.3% (women) 1 LUTS at least often: 79.99% (men), 52.5% (women)	LUTS (AUASI \geq 8): 18.7% (men), 18.6% (women); increased with age (10.5% for 30–39 years to 25.5% for 70–79 years), no difference by race/ethnicity (16.2%–19.3%)
BOTHER Rates of bother were lower for LUTS classified as at least “sometimes” than those classified as at least “often”; however, leaking urine during sexual activity, which was reported infrequently, was highly bothersome (82.1% men; 87.2% women), whereas terminal dribble, which was reported frequently, was less bothersome (40.6% men; 40.2% women)	Mean bother scores were higher in those with LUTS (vs. no LUTS) and for women vs. men
TREATMENT SEEKING Treatment seeking was low but most common in those in the voiding + storage + postmicturition subgroup: 29.1% men, 27.5% women; prescription medication use was also highest in this subgroup (17.6% and 10.4%, respectively)	Prescription medication use for urinary symptoms was low even among those with AUASI \geq 8, at 9.8% (men) and 2.1% (women)
COMORBIDITIES Comorbid conditions were most common in the voiding + storage + postmicturition subgroup, with significant associations for LUTS with arthritis, asthma, chronic anxiety, depression, diabetes (men only), heart disease, irritable bowel syndrome, neurologic conditions, recurrent UTI, and sleep disorders; childhood nocturnal enuresis was significantly associated with most LUTS subgroups	LUTS (AUASI \geq 8) was associated with heart disease, diabetes (men only), and depression

AUASI, American Urological Association Symptom Index; LUTS, lower urinary tract symptoms; UTI, urinary tract infection.

From Kaplan SA, Roehrborn CG, Chapple CR, et al. Implications of recent epidemiology studies for the clinical management of lower urinary tract symptoms. *BJU Int* 2009;103(Suppl. 3):48–57.

with increasing LUTS symptom severity (Fig. 103-14). While these correlations do not necessarily imply a causative mechanism, it is possible that similar pathophysiologic events underlie the development of both problems in the aging male, the most obvious being ischemia in both the genital and lower urinary tract organs (McVary, 2005). A logistical regression analysis of the EpiLUTS data also documented a strong relationship between various domains of sexual and ejaculatory dysfunction and LUTS (Wein et al, 2009) (Table 103-5).

Sidney (1987) analyzed the Kaiser Permanente database and initially found a relative risk (RR) of 1.2 for the diagnosis of BPH among men who had a vasectomy. However, after 5 years of follow-up, the RR was 0.97 and not significant. There does not appear to be a relationship between vasectomy and BPH development or prostate size (Jakobsen et al, 1988), and in the Massachusetts Male Aging Study, Meigs and coworkers (2001) did not find that vasectomy increased the risk of being diagnosed with BPH.

Alcohol and Liver Cirrhosis

Alcohol may decrease testosterone production and plasma testosterone levels and increase clearance of testosterone (Chopra et al, 1973). Despite this hypothetical reason for a lower incidence of BPH in men who drink, inverse relationships have been described. Both Morrison (1992) and Sidney and colleagues (1991a) reported

by multivariate analysis an adjusted RR of 0.49 and age-adjusted RR of 0.75, respectively, for the risk of having surgery for BPH when taking in more than three glasses of alcohol per day. However, one might argue that the poorer health in heavy drinkers might bias physicians against surgery. Glynn and coworkers (1985) in fact found no increased risk for either the clinical diagnosis or surgical rates. A recent analysis of the Prostate Cancer Prevention Trial also showed an inverse relationship between a diagnosis of BPH and alcohol intake, that is, a somewhat protective effect (Kristal et al, 2008). A meta-analysis of alcohol intake, BPH, and LUTS demonstrated that consumption of alcohol decreases the likelihood of BPH, but not LUTS, in all six strata. Compared with no alcohol, an alcohol intake of 36 g/day or greater was associated with a 35% decreased likelihood of BPH (OR 0.65) (Rees, 2009).

Of five studies examining the relationship between liver cirrhosis and BPH based on autopsy material, four found a lower prevalence of BPH in men with cirrhosis (Bennett et al, 1950; Stumpf and Wilens, 1953; Robson, 1966; Frea et al, 1987), while one study—admittedly with some design flaws—found a higher prevalence (Wu, 1942). Since most cirrhosis cases are alcohol induced, the separation of the effects of alcohol versus cirrhosis is virtually impossible.

On the other hand, nonalcoholic fatty liver disease, which is part of the metabolic syndrome, is associated with BPH in men and with overactive bladder in women (Uzun et al, 2013).

Figure 103-14. Erectile function (A) decreases and ejaculatory disturbances (EJ; B) increase with advancing age, but within each decade of life they also decrease and increase, respectively, with increasing severity in lower urinary tract symptoms (LUTS). DAN-PSS-Sex, Danish Prostatic Symptom Score; IIEF, International Index of Erectile Function. (From Rosen R, Altwein J, Boyle P, et al. Lower urinary tract symptoms and male sexual dysfunction: the multinational survey of the aging male [MSAM-7]. *Eur Urol* 2003;44:637-49.)

Hypertension

The sympathetic nervous system, via α -adrenergic fibers and receptors, plays an important role in both hypertension and the symptoms of BPH. However, since both hypertension and LUTS/BPH increase with advancing age, it is difficult to prove a causal relationship between these two conditions (Boyle and Napalkov, 1995). The previously cited studies by Glynn and Sidney and their colleagues (Glynn et al, 1985; Sidney et al, 1991a) did not find an association. In a small clinic cohort study with methodologic flaws, Pressler and associates (1997) reported an increase in the incidence of hypertension of 15%, 18%, and 31% for men with mild, moderate, and severe symptoms. Autonomic hyperactivity has been implicated in the development of both LUTS and ED in the aging male, but conclusive clinical data are lacking (McVary et al, 2005). In the EpiLUTS study, both heart disease and hypertension were associated with more severe LUTS symptom constellations (Coyne et al, 2009).

Further studies are needed to better understand the common underlying pathophysiologic mechanisms and a potential cause-and-effect relationship.

Smoking

Smoking cigarettes appears to increase both testosterone and estrogen levels because of the nicotine level, and thus should have a positive and inductive effect on the development of BPH. However, since severe smoking causes other health problems, surgery rates are probably a poor indicator for a possible correlation, since physicians are biased against surgery in heavy smokers. Seitter and Barrett-Connor (1992) indeed found no correlation between smoking and prostatectomy rates, and Glynn and associates (1985) failed to identify a correlation between smoking and the clinical diagnosis of BPH. Sidney and coworkers (1991a) followed 16,000 men over 15 years and found a negative correlation between being a smoker at baseline and subsequent risk of prostatectomy. Daniell (1993a) examined the records of 345 patients who underwent prostatectomy and found smaller gland volumes in smokers and a lower age-adjusted prevalence of ever-smokers compared to a control group. Roberts and colleagues examined this issue in the Olmsted County Study (Roberts et al, 1994a) and later in a Japanese population (Roberts et al, 1997b). In Olmsted County only 16% of the over 2000 men in the study were current smokers, which appears low but understandable considering the population mix in Rochester, Minnesota. A biphasic association was found, with light to moderate smokers being less likely to have moderate to severe LUTS, and heavy smokers having at least the same risk as never-smokers.

An update from the Olmsted County Study suggests that smoking is associated with decreased urinary flow rates and moderate to severe symptoms, but not with enlarged prostate volume or increasing serum PSA (Rule et al, 2005). This is in contrast to earlier studies suggesting a relationship between smoking and prostate size (Kupeli et al, 1997). In the EpiLUTS study, ex-smokers had an increased risk of having more severe symptom constellations and never-smokers had a decreased risk, while the risk for current smokers was not a factor (Coyne et al, 2009).

Recent evidence from the Olmsted County Study verified the absence of a meaningful clinical association between current smoking and urinary retention (Sarma et al, 2009), and in the BACH survey no correlation between smoking and LUTS was observed (Maserejian et al, 2012).

Any relationships between current or past smoking and LUTS/BPH are likely to be weak and of limited clinical significance.

Physical Activity, Diet, Obesity, Body Mass Index, and the Metabolic Syndrome

Chyou and coworkers (1993) examined 33 food items in relationship to prostatectomy rates, and found only beef intake to be significantly associated. Araki and colleagues (1983) reported increased clinical diagnosis of BPH in men with higher milk consumption and lower consumption of green and yellow vegetables. Overall, there is no convincing evidence for any individual diet factor to play a major role in the development of LUTS/BPH.

The relationships between LUTS/BPH and obesity, body mass index (BMI), and the metabolic syndrome have recently been of great interest (Hammarsten et al, 1998; Hammarsten and Hogstedt, 1999, 2001; Rohrmann et al, 2005; Gupta et al, 2006; Kasturi et al, 2006). Metabolic syndrome is a clinical constellation of metabolic abnormalities, including obesity, glucose intolerance, dyslipidemia, and hypertension, that increase the risk of cardiovascular disease and result primarily from modifiable risk factors, particularly physical inactivity and dietary practices endemic to Westernized societies (Haffner and Taegtmeier, 2003). There are plausible biologic considerations: adipose tissue is the main source of aromatization of testosterone to estrogen, and men with lower BMI have higher serum testosterone levels (Eldrup et al, 1987).

‡Not having a history of prostatitis is associated with premature ejaculation.

From Wein AJ, Coyne KS, Tubaro A, et al. The impact of lower urinary tract symptoms on male sexual health: EpiLUTS. BJU Int 2009;103(Suppl. 3): 33–41.

BMI was negatively associated with surgically treated BPH in the Kaiser Permanente cohort study (Sidney et al, 1991a), and with a clinical diagnosis of BPH in the Normative Aging Study (Glynn et al, 1985). In contrast, in a study of 68 men by Soygur and coworkers (1996), the average prostate weight increased both with age and with increasing obesity together with an increase in serum estradiol levels. Daniell (1993b) also found larger adenomas in more obese men undergoing prostatectomy. Both of these studies report a positive correlation between obesity and prostate size, but neither between obesity and symptom severity. Several caveats must be mentioned: DRE is less likely to yield a diagnosis of BPH and prostate enlargement in very obese patients due to anatomic obstacles, and patients with high BMI may be biased against surgical interventions.

Men ages 40 to 75 years who were participants in the Health Professionals Followup Study and who were without prior diagnosis of cancer or prostatectomy provided data on weight, height, and waist and hip circumferences. After adjustment for age, smoking, and BMI, abdominal obesity was related to prostatectomy (OR 2.38) and to frequent urinary symptoms among those without prostatectomy (OR 2.00). BMI, hip circumference, and waist-to-hip ratio were not associated with BPH independently of waist circumference. **These results suggest that abdominal obesity in men may increase the frequency and severity of urinary obstructive symptoms and may increase the likelihood that such obese men will undergo a prostatectomy** (Giovannucci et al, 1994).

Hammarsten and Hogstedt (1999) examined 250 patients with LUTS and found non-insulin-dependent diabetes mellitus, hypertension, tallness, obesity, high insulin levels, and low levels of high-density lipoprotein cholesterol to be risk factors for the development of BPH. They suggested a causal relationship between high insulin levels and the development of BPH, and hypothesized increased sympathetic nerve activity in men with BPH. In a hospital-based case-control study, overweight was modestly inversely related to BPH. The hypothesis of reduced testosterone levels in obese individuals may explain the different BPH risk and the need to be tested (Zucchetto et al, 2005). Parsons (2007) performed a comprehensive literature review and found that factors that potentially increase the risk of BPH and LUTS include obesity and diabetes, while factors that potentially decrease the risk include increased physical activity and moderate alcohol consumption (Table 103-6). Parsons and Kashefi (2008) also performed a comprehensive literature review and found eight studies ($N = 35,675$) that were eligible for a pooled analysis of the effect of physical activity levels stratified into light, moderate, and vigorous categories, with a sedentary category for reference. Compared to the sedentary group, the pooled ORs for BPH or LUTS were 0.70, 0.74 and 0.74 for men engaging in light, moderate, and heavy physical activity, respectively. Physical activity thus appears to reduce the risks of BPH and LUTS. Similar findings of increased likelihood of LUTS with increasing BMI and decreasing likelihood with greater physical activity were also reported from the EpiLUTS study (Coyne et al, 2009).

The evidence at present suggests a positive relationship between lack of physical activity, obesity, BMI, and other measures of the metabolic syndrome and both LUTS and BPH (including prostate volume), while increased physical activity appears to have a protective effect.

Medications

Very limited information is available. Cold medications containing α -sympathomimetic drugs exacerbate LUTS by the expected effect on the smooth muscles of the bladder outlet. A careful analysis of the data from the Olmsted County Study demonstrated that daily use of antidepressants, antihistamines, or bronchodilators is associated with a 2- to 3-point increase in the IPSS compared to age-matched nonusers, and daily use of antidepressants is associated with a decrease in the age-adjusted flow rate (Su et al, 1996).

Correlations between Parameters

As noted, all relevant parameters such as symptom severity and frequency, bother, interference, disease-specific HRQOL, maximum flow rate, and prostate volume tend to worsen with advancing age. However, reported correlations between these parameters as well as urodynamic pressure-flow studies are in general weak with some exceptions. Strong correlations exist, as one might expect, between subjective measures such as symptom severity and frequency (IPSS score), bother, disease-specific HRQOL, and interference scores (Barry et al, 1995b; Girman et al, 1999) (Fig. 103-15).

Weak numerical correlations can arise artifactually, regardless of whether true physiologic relationships exist (Girman, 1998). Correlations are further affected by intraindividual variability of measured parameters, day-to-day variability, measurement errors associated with the technique or equipment, or the natural history of the condition itself (Bruskewitz et al, 1982; Diokno et al, 1992; Barry et al, 1995c; Sagnier et al, 1996).

It is furthermore crucial to consider the population utilized to evaluate correlations. A correlation is more easily identified if patients exhibiting the full spectrum of the parameters of interest are included. In most LUTS/BPH studies, however, patients are excluded based on thresholds imposed, making it more difficult for a significant correlation to emerge. There are many examples in clinical medicine in which weak numerical correlations exist but strong clinical relationships are well accepted (Wilson and Cleary, 1995).

The absence of meaningful baseline correlations for symptoms, flow rate, and prostate volume in a tightly controlled population of men with LUTS and BPH enrolled in a BPH treatment study is shown in Table 103-7.

An example of how restriction of the full range of parameters affects correlations is shown in Figure 103-16. Volunteers without known prostatic diseases were asked to fill in an AUASI score and perform a flow rate recording. When all data are considered, a clear relationship exists, with the maximum flow rate decreasing with increasing symptom severity ($r = 0.4$; $P < .05$). However, when considering only those patients typically seen in a BPH study, namely, those with a score above 10 points and a maximum flow rate between 5 and 15 mL/sec, the correlation within that cohort exhibiting a limited range of observation on both scales is very weak ($r = 0.08$; not significant) and the regression line becomes flat (see Fig. 103-16).

The correlations observed between symptoms, flow rate, and prostate volume in true community-based population studies without artificially imposed entry criteria are consequently somewhat higher than those seen in BPH clinic or trial populations. In the Olmsted County Study, after adjusting for age, the odds of moderate to severe symptoms were 3.5 times greater for men with prostatic enlargement (>50 mL) than for men with smaller prostates, while the odds were similarly increased (2.4-fold) for men not achieving a peak urinary flow rate of 10 mL/sec (Girman et al, 1995). Men with enlarged prostates were about twice as likely to have bother due to symptoms (OR 2.4) or activity interference (OR 1.8) relative to men with smaller prostates (Girman et al, 1999). In a similar study from the Netherlands, Bosch and coworkers (1995b) reported numerically weak but statistically significant correlations between the IPSS and TPV ($r = 0.19$, $P < .001$), peak flow rate ($r = -0.18$, $P < .001$), and postvoid residual urine volume ($r = 0.25$, $P < .001$).

While weak correlations between prostate volume and symptoms as well as flow rate have been accepted, attention has also focused on correlations between the transition zone of the prostate and physiologic measures. A stronger correlation between the transition zone and symptoms ($r = 0.48$, $P = .03$) and peak urine flow ($r = -0.34$, $P = .05$) was reported first by Kaplan and colleagues (1995), who also showed a significant correlation between transition zone index (TZV/TPV) and symptoms ($r = 0.75$), peak urine flow ($r = -0.71$), and—somewhat unexpectedly—detrusor pressure at peak urine flow ($r = 0.43$). These data were generated from a relatively small cohort of 61 men with BPH. Invasive pressure-flow

TABLE 103-6 Cohort Studies of Modifiable Risk Factors Associated with Decreased or Increased Risk of LUTS and/or BPH

STUDY	OUTCOME MEASURE (RISK FACTOR)	REFERENCE CATEGORY	OR (95% CI)
DECREASED RISK OF BPH AND LUTS			
Health Professionals Follow-up Study	Clinical BPH:		
	Alcohol intake 30.1-50 g/day	Alcohol intake 0 g/day	0.59 (0.51-0.70)
	Walking ≥ 2 hr/wk	Walking 0 hr/wk	0.73 (0.63-0.84)
Massachusetts Male Aging Study	Clinical BPH (physical activity 862 kcal/day or greater)	Physical activity ≤ 140 kcal/day	0.50 (0.3-0.9)
Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial	Clinical BPH (alcohol intake ≥ 60 g/day)	Alcohol intake < 5 g/day	0.60 (0.5-0.7)
	TURP likelihood (alcohol intake ≥ 60 g/day)	Alcohol intake < 5 g/day	0.40 (0.3-0.7)
	Nocturia (alcohol intake ≥ 60 g/day)	Alcohol intake < 5 g/day	0.80 (0.7-1.0)
Third National Health and Nutrition Examination Survey (NHANES III)	LUTS:		
	Alcohol intake ≥ 1 drink/day	Never	0.59 (0.36-0.97)
	Physical activity > 6 times/wk	Physical activity 0 times/wk	0.49 (0.29-0.84)
INCREASED RISK OF BPH AND LUTS			
Baltimore Longitudinal Study of Aging	LUTS:		
	Diabetes	No diabetes	2.80 (1.10-7.10)
	Fasting glucose > 110 ng/dL	Fasting glucose ≤ 110 ng/dL	2.60 (1.01-6.70)
	Prostate ≥ 40 mL:		
	BMI > 35 kg/m ²	BMI < 25 kg/m ²	3.52 (1.45-8.56)
	Diabetes	No diabetes	2.25 (1.25-4.11)
	Fasting glucose > 110 ng/dL	Fasting glucose ≤ 110 ng/dL	2.98 (1.70-5.23)
Flint Men's Health Study	LUTS:		
	Diabetes	No diabetes	1.95 (1.49-2.57)
	Hypertension	No hypertension	1.29 (1.04-1.61)
Health Professionals Follow-up Study	BPH surgery (waist circumference > 109 cm)	Waist circumference < 89 cm	2.38 (1.42-3.99)
	LUTS (waist circumference > 109 cm)	Waist circumference < 89 cm	2.00 (1.47-2.72)
Second Nord-Trøndelag Health Study (HUNT-2)	LUTS:		
	BMI ≤ 40 kg/m ²	BMI < 25 kg/m ²	1.79 (0.90-3.56)
	Diabetes	No diabetes	1.25 (1.04-1.49)
	Waist/hip ratio ≤ 0.94	Waist/hip ratio ≤ 0.85	1.32 (1.15-1.50)
NHANES III	LUTS:		
	Diabetes	No diabetes	1.67 (0.72-3.86)
	Hypertension	No hypertension	1.76 (1.20-2.59)
	Increase in BMI between age 25 yr + highest BMI ever	No increase	1.90 (0.89-4.05)
	Waist circumference > 102 cm	Waist circumference < 94 cm	1.48 (0.87-2.54)

BMI, body mass index; BPH, benign prostatic hyperplasia; CI, confidence interval; LUTS, lower urinary tract symptoms; OR, odds ratio; TURP, trans-urethral resection of the prostate.

studies are not performed in community-based studies, and thus comparative data from population-based studies cannot be reviewed. However, the finding of a relationship between measures of obstruction and prostate volume is rare, with most authors denying such a relationship in series of BPH clinic or trial patients (Bosch et al, 1995c; Yalla et al, 1995; Ezz el Din et al, 1996; Witjes et al, 1997; d'Ancona et al, 1998; Homma et al, 1998; Kuo, 1999; Steele et al, 2000). Data from the Olmsted County Study suggest no stronger correlation between symptoms and peak flow rates with TZV ($r = 0.17$, $P = .001$ and $r = -0.20$, $P < .001$, respectively) than with TPV ($r = 0.16$, $P < .001$ and $r = -0.16$, $P < .001$, respectively). The TZV/TPV weakly correlated with the AUASI ($r = 0.08$, $P = .103$) and peak urinary flow rate ($r = -0.08$, $P = .0823$) (Corica et al, 1999). In a large BPH treatment trial, the TZV also did not correlate more strongly with other measures compared to the TPV.

The correlation between serum PSA and prostate volume, both total and transition zone, has recently been described in greater

detail (Roehrborn et al, 1999b). Although the individual variability is significant, precluding an accurate prediction of prostate volume by serum PSA in individual patients, there is a strong log-linear relationship between these parameters that can be shown in both population-based and clinical studies (Hochberg et al, 2000; Morote et al, 2000; Hedelin et al, 2005). The relationship is further influenced by patients' age, with older patients having a greater increase in prostate volume per unit of serum PSA (Fig. 103-17). In Asian men similar relationships exist; however, in general both prostate volume and serum PSA tend to be smaller/lower (see Fig. 103-17B) (Gupta et al, 2005). Relationships between other PSA-derived parameters have recently been examined, and a certain subform of PSA (BPSA) has been shown to be more strongly related to BPH compared to total serum PSA (Canto et al, 2004).

With the exception of age, correlations between various measures of LUTS and BPH are modest in community-based population studies and weak in BPH clinic and trial populations. The

Figure 103-15. TPV					0.775 <0.0001

BPH, benign prostatic hyperplasia; IPSS, International Prostate Symptom Score; PSA, prostate-specific antigen; Q_{max}, peak flow rate; TPV, total prostate volume; TZV, transition zone volume.

*This study included 2800 men older than age 50 years, an IPSS score >12, Q_{max} <15 mL/sec, serum PSA between 1.5 and 10 ng/mL, and TPV >30 mL (TZV not specified). Note the lack of strong correlations except for age and serum PSA versus volume between parameters.

Figure 103-16. Correlation and regression (95% confidence interval) between symptom score and maximum flow rate (Q_{max}) in volunteers ($r = 0.4$; $P < .05$). When only those volunteers with a symptom score above 10 points and a flow rate between 5 and 15 mL/sec (●) are considered, the correlation is virtually absent ($r = 0.08$; not significant), as indicated by a flat regression line (black). AUASI, American Urological Association Symptom Index.

Figure 103-17. Prediction of prostate volume based on serum prostate-specific antigen (PSA) stratified by age in white men (A) and in Japanese men (B). (A, From Roehrborn CG, Boyle P, Gould AL, et al. Serum prostate-specific antigen as a predictor of prostate volume in men with benign prostatic hyperplasia. *Urology* 1999;53:581–9; B, from Gupta A, Aragaki C, Gotoh M, et al. Relationship between prostate specific antigen and indexes of prostate volume in Japanese men. *J Urol* 2005;173:503–6.)

relationship between serum PSA and prostate volume is moderate, and influenced by age and race and ethnic origin. Neither symptoms nor flow rate nor prostate volume measures can predict presence and degree of obstruction reliably.

NATURAL HISTORY OF UNTREATED BENIGN PROSTATIC HYPERPLASIA

The natural history of a disease process refers to the prognosis of the disease over time. In other words, the measurement of changes in parameters of interest and the incidence rates of significant outcomes constitute what is commonly referred to as the natural history of a disease. It is important for clinicians to gain as good an understanding as possible of the natural history of any illness, since the benefits and risks of any therapeutic interventions should always be balanced with the risks involved in just watching the disease (i.e., the natural history). In fact, the degree to which natural history must be studied depends on the seriousness of the disease, as well as the risks involved with the therapeutic intervention. For example, it proves to be crucial to understand the natural history of abdominal aortic aneurysms and how their prognosis is determined by their size in order to adequately counsel patients regarding surgical interventions, which have considerable risks in themselves.

Clinical Parameters and Outcomes of Interest

Table 103-8 lists the beneficial and harmful changes in measurable parameters and outcomes, which are of interest in both the natural history and treatment of LUTS and BPH. They may be divided further into direct or biologic and indirect or proxy outcomes (Eddy, 1990, 1992). The biologic or direct outcomes are those that are immediately noticeable by the patients (e.g., symptom changes, infections, death), while the indirect or proxy outcomes are not directly noticeable but may predict future changes in direct outcomes (e.g., changes in pressure-flow parameters may predict episode of retention). The parameters and outcomes are dichotomous (yes or no, e.g., retention or no retention), categorical (grades of severity, e.g., grades of obstruction measured by pressure-flow studies), or continuous (scales of severity, e.g., symptom score, maximum flow rate). Accordingly, the most common ways to measure such outcomes are probabilities or rates of occurrences for

TABLE 103-8 Beneficial and Adverse Changes in Parameters and Outcomes

BENEFICIAL CHANGES		HARMFUL CHANGES	
Probability of symptom improvement	D D	Probability of symptom worsening	
Magnitude of symptom improvement	D Co	Magnitude of symptom worsening	
Magnitude of bother improvement	D Co	Magnitude of bother worsening	
Magnitude of quality-of-life improvement	D Co	Magnitude of quality-of-life worsening

dichotomous or categorical outcomes, and measures of central tendency (mean or median) and variability (standard deviation or standard error or CI) for outcomes measured by continuous scales.

Methods of Studying Natural History of Benign Prostatic Hyperplasia

The natural history of BPH can theoretically be evaluated by studies of a variety of designs:

- Longitudinal studies of untreated cohorts of men diagnosed with LUTS and clinical BPH by any definition (*watchful waiting cohorts*)
- Studies of the behavior of men diagnosed with LUTS and BPH and enrolled in controlled studies of LUTS and BPH (*control groups*) and receiving either
 - no treatment (compared to active intervention),
 - placebo treatment (compared to medical treatment), or
 - sham treatment (compared to device or surgical treatment)
- Longitudinal studies of unselected (i.e., undiagnosed) men living in the community who are less likely to progress and request or require therapy (*longitudinal population-based studies*)

There are problems associated with either of the approaches. Concerning the *watchful waiting cohorts*, the first question to be resolved is whether or not it is ethical (or feasible) to enroll symptomatic men in such a study even if the disease studied is not fatal. Second, the very fact that the patients had an initial and presumably subsequent contacts with health care providers in the course of the study will bias them, leading to changes in outcome parameters of interest presumably different from those observed in an age-matched cohort of men similar in all parameters at baseline, but who did not choose to participate (a cohort one might call, in analogy to genetic language, “wild-type”). Further, many diagnosed men will in the course of such natural history study become more and more symptomatic and therefore desire and receive treatment, making them ineligible to further participate in the study and thus reducing the number of men available for analyses. Lastly, a very important bias is introduced by the fact that patients in such cohorts are selected based on thresholds imposed by inclusion and exclusion criteria. In general, patients are selected to participate who are more symptomatic, that is, those with higher symptom scores and lower maximum flow rates. By the principle of trial conduct, patients then repeat the symptom and flow rate assessment during follow-up (or after treatment). However, the same inclusion/exclusion criteria are not applied to the follow-up measurements,

which leads to a unilateral regression to the mean, suggesting (falsely) an improvement in the parameter of interest.

To determine the effect that the stringency of pretrial screening has on the outcome of placebo treatment, a cohort of 145 volunteers were invited to fill in the IPSS score and perform a flow rate recording twice within a month without receiving any therapy or instructions whatsoever (Sech et al, 1998). Although many patients experienced either an increase or a decrease in both parameters, the mean values did not change significantly (IPSS 12.1 vs. 11.7 points, peak flow rate 17.7 vs. 17.4 mL/sec; not significant). However, when typical BPH trial conditions were applied and only those patients who had an IPSS score above (>7, >10, >15) and a flow rate below (<15, <12, <10 mL/sec) a certain threshold were considered for analyses, a unilateral regression to the mean took place by which the “more” symptomatic volunteers (i.e., patients) still experienced considerable natural variability on the occasion of the second assessment, but the net effect was toward “improvement,” that is, lower scores and higher flow rates. For example, when only considering patients with IPSS scores greater than 10 points, the mean difference between first and second assessment was between 19.9 versus 18.8 points or –1.1 (*P* < .05). Similarly, when only patients with a peak flow rate less than 12 mL/sec were considered, the mean difference between the first and second assessment was 9.3 versus 10.9 mL/sec or +1.6 mL/sec (*P* < .01) (Table 103-9).

This experiment clearly illustrates that a unilateral regression to the mean induced and controlled by the stringency of the inclusion criteria can result in a significant “improvement” in any parameter for which a threshold is set at the baseline screening. Such purely mathematical effect is likely at work in many if not all studies where the outcome parameters are measured using a numerical scale of some sort, and where baseline screening criteria are applied.

Control groups of men being randomized to receive either no treatment, placebo treatment, or sham treatment, while being compared to a matched group of men receiving active therapeutic interventions, also suffer from a variety of biases. As with the *watchful waiting cohorts*, they have initial and constant contact with health care providers and know from the design of the study that they are randomized to the perceived less effective or ineffective arm, and thus they may have a lower threshold than community-dwelling men to cross over to active therapy. On the other hand, owing to a sense of obligation, they may elect to be followed until the trial is over, and then choose an active treatment. They are also subject to the regression to the mean bias discussed before, since they were subjected to inclusion/exclusion criteria.

Longitudinal population-based studies, although difficult and expensive to conduct, are likely the best vehicle to understand

TABLE 103-9 Effect of Stringency of Pretrial Screening on Outcome of Placebo Treatment*

the natural history of the disease. The regression to the mean bias does not apply, as the participants are not selected based on inclusion and exclusion thresholds. Since no formal diagnosis is established, the natural history may take place unencumbered by preconceived notions about symptoms, end points of trials, and anything else leading to a bias in a watchful waiting cohort of diagnosed and thus labeled men or in a control group of diagnosed men. One must realize, however, that the very need to monitor the natural history—that is, the need to ask questions and perform tests and interventions—conflicts with the notion of the “natural history,” and thus some biases are likely to be unavoidable even in the most ideal setting.

Watchful Waiting Studies

Following cohorts of men diagnosed with LUTS and/or BPH conservatively (*watchful waiting cohorts*) was attempted by some investigators in the past, but the few published reports are of limited scientific rigor and informational value, and have significant shortcomings. Inclusion and exclusion criteria are poorly defined, follow-up and compliance are poor, assessment instruments are either not defined or insufficient, and patient accounting is incomplete. The studies do provide answers regarding the probability of symptom changes and the magnitude of flow rate changes.

Five such studies were reported between 1919 and 1988 with a total enrollment of 456 patients and a follow-up ranging from 3 to 6 years (Clarke, 1937; Craigen et al, 1969; Birkhoff et al, 1976; Ball et al, 1981; Kadow et al, 1988). A change in symptom status was reported for all 456 patients, while none of the studies utilized a quantitative symptom severity scale. Data on urinary flow rate and residual urine were available for 223 and 197 patients, respectively. The peak urinary flow rate deteriorated in 66% and improved in 20%. Residual urine increased (35%), decreased (37%), and remained unchanged (28%) in about the same number of all patients. The mean change in peak flow rate (in those patients for whom data are available) was +2.2 (from a mean of 9.0 to 11.2) mL/sec or 24%, while the mean change in residual urine was +37 (from a mean of 115 to 152) mL or 32%. Data on symptom improvement were reported as a dichotomous outcome (improved versus not improved). The mean probability for any improvement in symptom severity in these studies is 42.5% (90% CI 30.8 to 54.8) as calculated by meta-analytical methods (Eddy and Hasselblad, 1992).

A superior approach, namely to follow a *no-treatment control group* of men diagnosed with LUTS and BPH, was chosen by Wasson and coworkers (1995). A total of 556 men with moderate symptoms and a Madsen-Iversen symptom score between 10 and 20 points (0- to 27-point scale) were randomized to either undergo transurethral resection of the prostate (TURP) or be watched conservatively. There were 47 treatment failures (defined as death, recurrent infection, residual urine volume over 350 mL, development of bladder calculus, incontinence, a symptom score of 24 or higher, or a doubling of serum creatinine from baseline) in the watchful waiting arm ($N = 276$) versus 23 in the surgery arm ($N = 280$) over 3 years of follow-up (RR 0.48, 95% CI 0.3 to 0.77). Sixty-five (24%) of the men assigned to watchful waiting underwent surgery during follow-up, 20 of them for treatment failure. The majority of these men were classified as more bothered at baseline, and about 40% of patients in this category experienced an improvement in the degree of bother from urinary difficulties, a proportion strikingly similar to the overall estimate of 42.5% from the natural history studies. At 3 years of follow-up, the patients randomized to watchful waiting who did not fail or cross over to surgery had a small but noticeable improvement in nearly all outcomes measured, including a +0.4-mL/sec increase in the maximum flow rate.

More recently, a 60-month update was reported providing data on 966 patient-years of follow-up on the TURP patients and 990 patient-years on the watchful waiting patients (Flanigan et al, 1998). The treatment failure rate was 21% for the watchful waiting group and 10% for the TURP group, and all outcomes were better for the TURP-treated patients (Table 103-10). During follow-up, 76 (27%) of the watchful waiting patients crossed over to TURP; the 5-year Kaplan-Meier estimate of the crossover rate was 36%, and twice as many patients crossed over electively as compared to post-treatment failure protocol-dictated crossover. The most significant factor predicting elective crossover was high baseline bother due to urinary symptoms (Fig. 103-18). When separately analyzed, the patients crossing over from watchful waiting to TURP had fewer improvements in outcome parameters compared to those randomized to TURP initially (Table 103-11). In many instances the differences between the groups were statistically and clinically significant. A reduction in symptom score by –11 points (high baseline symptom group) and an improvement in maximum flow rate by 8.7 mL/sec (low baseline flow rate group) after TURP is expected; however, in those men undergoing TURP after an unsuccessful trial of watchful waiting, the improvements were only –8 points and +4.7 mL/sec. This allows the speculation that, during the period of watchful

waiting prior to crossover, some irreversible damage might have occurred preventing symptom and flow rate improvements to the same degree as observed in those men initially treated by TURP.

Djavan and colleagues (2004) followed a group of 397 men presenting to a urology clinic with mild LUTS, defined as scoring less than 8 points on the IPSS. These men were followed for 4 years beginning with a watchful waiting protocol and were re-evaluated every 3 months for 48 months' total time. The cumulative incidence of clinical progression, defined as worsening of the IPSS with migration from mild to moderate (IPSS 8 to 18 points) or severe (IPSS 19 to 35 points) symptoms, was assessed. The likelihood of migrating or transitioning from one health state to another was 6%, 13%,

15%, 24%, 28%, and 31% at 6, 12, 18, 24, 36, and 48 months, respectively.

Placebo and Sham Control Groups in Randomized Trials

Data from control groups treated with placebo or sham and compared to matched groups of patients treated with medications or devices are available to address many of the parameters and outcomes of interest.

Placebo Control Groups. For the Clinical Practice Guideline for the diagnosis and treatment of BPH published by the Agency for Health Care Policy and Research (AHCPR) in 1994, data on 1417 patients treated in 45 placebo arms of placebo-controlled trials were analyzed (McConnell et al, 1994). Table 103-12 allows a direct comparison between the watchful waiting studies discussed above and these placebo groups, both summarized by meta-analytical techniques. For none of the examined parameters can a significant difference between the two treatment modalities be identified. However, several points deserve discussion. As opposed to the longer-term follow-up in the watchful waiting studies, the placebo studies are part of short- to mid-term medical treatment trials ranging from 3 days to 52 weeks in duration (mean 13 weeks). In all these studies the patients are blinded as to the treatment arm, and thus have in most cases at least a 50:50 (or better in cases of 2:1 or 3:1 randomization) chance of receiving active drug. Dropping out of such studies because of failure does not have the same ramification as it does in watchful waiting studies, where the patients willingly assumed a conservative treatment approach knowing that it might fail (i.e., they might fail and go on to active treatments). In contrast, in some placebo-controlled studies a promise—either tacit or openly—is made stating that, following the conclusion of the trial, either the patient would be eligible for “free” active treatment or he would be “moved up” on the surgical waiting list (this phenomenon is unique to those studies conducted in the United Kingdom). The inactive preparation given should theoretically add to the placebo effect, and thus improve the outcome above those noted for watchful waiting studies. The probability for a patient to experience improvement, however, is estimated to be about 40% in the uncontrolled watchful waiting studies, the randomized watchful waiting versus TURP study, and the combined placebo arms. The changes in peak flow rate and residual urine are similar, and similarly small, for these three groups as well. It becomes evident that 40% of patients report some improvement, and the minimal fluctuations of peak flow rate and residual urine represent the “placebo effect” background against which the more substantial changes in these parameters achieved by active treatment modalities must be seen.

Sham Control Arms of Device Treatment Trials for Benign Prostatic Hyperplasia. In recent years a multitude of minimally invasive device treatments for BPH have been developed and tested in randomized, sham-controlled, open, single-blind, or even double-blind trials. While the majority of these trials compare various types of heat treatments (transrectal or transurethral hyperthermia or thermotherapy) with a sham treatment, one investigator compared balloon dilation with “sham” cystoscopy alone in a randomized, double-blind trial involving 33 men with BPH (Lepor et al, 1992b).

The outcomes of the balloon dilation versus cystoscopy trial, one multicenter trial using transrectal or transurethral hyperthermia in comparison with a sham control (Abbou et al, 1994), and five transurethral microwave thermotherapy trials and their respective sham control arms can be used for analyses (Blute et al, 1993; Ogden et al, 1993a, 1993b; Bdesha et al, 1994; de la Rosette et al, 1994). Although the mean pretreatment severity score differed from trial to trial, the mean improvements in symptom severity in the sham groups ranged from 5.2% to 15.6% (on a 100% scale), while the active thermotherapy-treated patients had improvements ranging from 27.0% to 37.8%, or in most cases twice the improvement as the sham control. The multicenter hyperthermia trial represents the exception, in that the actively treated cohort had an

TABLE 103-12 Comparison of Outcomes after Watchful Waiting and Placebo Treatment

OUTCOMES	WATCHFUL WAITING	PLACEBO
Total no. of patients	456	1417
FLOW RATE		
Probability for flow rate increase	19.7%	35.8%
Probability for no change in flow rate	14.2%	41.1%
Probability for flow rate decrease	66.1%	23.1%
Mean pre- and post-treatment flow rate (mL/sec)	9.0-11.2	9.1-9.7
Difference (mL/sec) and percent change	+2.2/+24.4%	+0.6/+6.6%
RESIDUAL URINE		
Probability for decrease in residual urine	35.0%	38.0%
Probability for residual urine to remain unchanged	28.0%	26.1%
Probability for increase in residual urine	37.0%	35.9%
Mean pre- and post-treatment residual urine (mL)	115-152	87-76
Difference (mL) and percent change	+37/+32.2%	-11/-12.6%
SYMPTOMS		
Probability for symptom improvement	41.7%	41.7%
Probability for symptoms to remain unchanged	25.8%	53.5%
Probability for symptom worsening	32.4%	4.7%
Mean probability for symptom improvement*	41.7%	41.7%
90% CI for symptoms improvement*	30.8-54.8	26.3-65.1

CI, confidence interval.

*Calculated by confidence profile method using hierarchical Bayes (Eddy and Hasselblad, 1992).

Modified from McConnell JD, Barry MJ, Bruskewitz RC, et al. Benign prostatic hyperplasia: diagnosis and treatment. Clinical Practice Guideline No. 8. Rockville (MD): U.S. Department of Health and Human Services, Public Health Service, Agency for Health Care Policy and Research; 1994. p. 1-17.

improvement similar to the sham control group, which is well within the range of the other sham control trials. The changes in peak urinary flow rate followed a similar pattern. With few exceptions the changes in peak flow rate were either very modest improvements or deteriorations (0.5, 0.6, -0.2, and -1.0 mL/sec), while the active treatment arms reported substantial improvements with the exception of the hyperthermia trial.

Placebo/Sham Effect and Baseline Symptom Severity. An area of considerable interest is the question as to what degree the placebo/sham effect depends on the baseline status of the patients. This could pertain to baseline symptom severity, baseline bother, quality of life, baseline flow rate, and all other imaginable parameters. Although few investigators have thus far reported data stratified by baseline parameters, results from a multicenter, placebo-controlled, 12-month α -blocker trial (terazosin) can be analyzed (Roehrborn et al, 1996). While the active drug-treated cohort had almost twice the improvement within each stratum, the placebo-treated patients had improvements ranging from 1.4 points (4.6%) to 7.5 points (21.4%) in order of increasing baseline severity score. The improvement for the placebo cohort overall was 3.3 points (10.6%).

A similar increase in the placebo effect with increasing baseline symptom severity has been reported for patients treated with finasteride in Phase III trials (Gormley et al, 1992). It might be speculated that the baseline symptom severity may also affect the sham effect seen in device trials. This phenomenon might be due to increased expectations in patients with more severe baseline symptoms, or simply due to a regression to the mean.

Natural History and Disease Progression in Long-Term Placebo Arms. The distinction between changes in parameters and rates of outcomes observed in placebo and sham control groups versus the longitudinal population-based studies becomes blurred when the placebo control is carried out over a period of time long enough to allow natural history changes to take place and confound the situation.

The Proscar Long-Term Efficacy and Safety Study (PLESS) followed a cohort of over 3000 men with moderate symptoms and enlarged prostate glands randomized to treatment with finasteride 5 mg daily versus placebo over 4 years (McConnell et al, 1998). In most control arms, both placebo and sham, the combined placebo effect interfering with the natural history of the disease is maintained for the entire duration of the study. In this 4-year trial, however, both the mean symptom score and mean maximum flow rate slowly drifted back to baseline after a typical initial placebo response (McConnell et al, 1998). The changes occurring in measurable parameters after the initial placebo effect has taken place thus can be considered to represent the natural history of the disease. The rates of outcomes such as AUR or surgery, as well as changes in prostate volume, which are less or not at all susceptible to the placebo effect, are also valid measures of the natural history of the disease.

The almost 1500 men in the placebo arm of this trial allowed for a detailed analysis of the placebo response and the subsequent natural history stratified by baseline parameters. It had been shown that in men with BPH there is a relatively strong correlation between prostate volume and serum PSA. In PLESS, only 10% of patients underwent baseline and yearly volume measurements by endorectal coil MRI. Based on the assumption that serum PSA would be a good proxy parameter for prostate volume, the analysis was initially performed for serum PSA and based on all 1500 men treated with placebo.
